

TROPICAL DISEASES BULLETIN

ISSUED UNDER THE DIREC-
TION OF THE HONORARY
MANAGING COMMITTEE

VOL 46 (Nos 1-12)
JANUARY—DECEMBER, 1949

London
BUREAU OF HYGIENE AND TROPICAL DISEASES,
Keppel Street, W C 1

HONORARY MANAGING COMMITTEE

APPOINTED BY THE SECRETARY OF STATE FOR THE COLONIES

Chairman E. D. Friels, C.M.G. D.S.O. O.B.E., M.B., B.S.
(Chief Medical Officer Colonial Office)

Professor Patrick A. Buxton, C.M.G., M.A., M.R.C.S., L.R.C.P. D.T.M. & H., F.R.S.
(representing the Royal Society)

Lieut.-General Sir James Bennett Haecce, K.C.I.E., O.B.E., M.D. F.R.C.S.E., K.H.S.,
I.M.S. (retd.)

Sir Wilson Jameson, G.B.E., K.C.B., M.D. M.D. F.R.C.P. M.I.P.
(representing the Ministry of Health)

Professor G. Macdonald, M.D., M.R.C.P. D.P.H., D.T.H.

Professor J. M. MacIntosh, M.D. F.R.C.P. D.P.H.

Sir Philip Mason-Baker, C.M.G., D.S.O. M.D. F.R.C.P., D.T.M. & H.

Sir Edward Mellanby, G.B.E., K.C.B., M.D. Sc.D. F.R.C.P. F.R.S.
(representing the Medical Research Council)

E. R. A. Merrett, C.B.E., M.D., F.R.C.P. F.R.S.E.

Brigadier G. S. Parkinson, C.B.E., D.S.O. M.R.C.S., L.R.C.P. D.P.H., late R.A.M.C.

J. B. Siddons, C.M.G. M.A. (of the Colonial Office)

Secretary J. C. Botton (of the Colonial Office)

STAFF OF THE BUREAU

Director Charles Wilcock, M.D. M.R.C.P. D.T.M. & H.

Assistant Director H. J. O'D. Burke-Gaffney O.B.E., M.D.

Secretary R. L. Sheppard, O.B.E.

Winifred F. Coventry

Alma D. Crump

Emily M. Duggan

ERRATA

Vol. 46, No. 2, p. 184 last para For "The average annual cost amounted to \$ 43 per house, or 0.637 per caput" read "The average annual cost amounted to \$5.43 per house, or \$0.637 per caput"

Vol. 46, No. 3 p. 272, in translation of LEON's title for *R. equatorius* read *R. equatoriensis*.

Vol. 46, No. 8, p. 753, in the abstract of the paper by HALAWANI *et al.*, the symbol "mgm." should read "µgm" in the following positions

para 1 lines 14 and 17

para 2, lines 9 and 10.

Vol. 46, No. 12, p. 1119 In the abstract of the paper by GAHAN DOWNS & CELIS the word "not" on the seventh line from the end should be omitted. The sentence beginning on the previous line should therefore read "It is evident that the DDT applications did kill enough adult mosquitoes"

TROPICAL DISEASES BULLETIN

[No 1]

SUMMARY OF RECENT ABSTRACTS*

I CHOLERA

Epidemiology

ARDOL (p 175) describes the origin and course of the recent epidemic of cholera in Egypt. In one month there were 8,408 cases and 3,230 deaths, and the disease was spread from its original focus by escaping settlers and by contaminated dates. In the *Lancet* (p 175) it is stated that main water supplies do not seem to have played any part in spread, but that badly constructed shallow wells did so to some extent. Treatment of patients by replacement of water and salt was the most important therapeutic measure, sulphonamides were on the whole disappointing. The value of vaccination was confirmed. In another article in the same issue of the *Lancet* the point is made that existing quarantine measures have been based on an incubation period of 5 days, and an average period of 5 days for excretion of vibrios, the rapid advance of air travel seems to demand a significant alteration of these measures.

In the *Chronicle of the World Health Organization* (p 333) there is an account of the Egyptian outbreak of cholera, which increased for 5 weeks, and then after declined. In 8 weeks there were 20,877 cases and 10,265 deaths. A noteworthy point is that the disease failed to establish itself in any town provided with a satisfactory water supply and an adequate sewage system in spite of repeated introduction from the villages.

BIRALD and KIVUL (p 426) of the World Health Organization discuss the epidemiology of cholera in relation to the Egyptian outbreak. The source of the epidemic is still obscure but there is a suggestion that a carrier of the vibrio may have travelled to Egypt from India by air. The focal point was overcrowded with people not normally resident there, and they straggled and spread the disease widely. Large cities escaped the outbreak because water supplies and sanitation were satisfactory. Graphs of the outbreaks of 1902 and 1947 are very similar, yet in 1902 there was no vaccination, which was widely used in 1947. FAYLOR (p 599) makes the point that there is no definite information on how cholera reached Egypt, but that it was presumably by air or sea.

WAHID (p 998) found 16 positive results in 600 contacts examined in Egypt, 12 of them were carriers for only 2 days, and the longest period was 7 days. Only 3 contacts showed evidence of the disease.

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1948, v 45. References to the abstracts are given under the names of the authors quoted, and the pages on which the abstracts are printed.

UNDERWOOD (p. 599) has written an account of the history of cholera in Great Britain.

Aetiology

SHRIVASTAVA and WHITE (p. 334) have examined various strains of vibrios. They quote their results showing that for instance an Inaba strain can be produced by growing an Ogawa strain in the presence of Ogawa mono-specific antiserum. They hold that the existing classification of the vibrios is taxonomically invalid and that it is probably merely expressing the range of natural variation of a single organism. The paper should be read in full. WHITE (p. 599) again expresses the opinion, formed as a result of his own recent work, that the known types of cholera vibrios are not separate species, but phases of a single species. He agrees with TAYLOR that in 311 strain magnetinable with O group 1 serum there was no evidence of choleric activity (except possibly in one strain).

REIDMAN (p. 74) thinks that in cholera epidemics either a single type strain or different serological types of the cholera vibrio are concerned. He discusses the possibilities.

The Horain strain of *V. cholerae* from Egypt was of Inaba type. GOMAR and MARKAWI (p. 705) point out that it does not live long inside dates, probably because acid is produced by fermentation of carbohydrates. The same authors (p. 706) examined the viability of the vibrio on various articles of food and clothing: there was a high correlation between the time of collection of dates and the time of the outbreak. Experiments by GOMAR *et al.* (p. 807) in Egypt indicate that the cholera vibrio lives no longer than 24 hours in sea water at 18°C. but that there may be an antibacterial substance in the sea-water which can be destroyed by autoclaving but cannot be removed by Seitz filtration.

BLAS (p. 176) having studied the metabolism of glucose by non-proliferating vibrios, thinks that the ratio of CO₂ produced to glucose consumed is too variable to be useful in distinguishing *V. cholerae* from the El Tor vibrio. GALLUT (p. 177) has continued his researches on the utilization of glucose by *V. cholerae* under aerobic conditions. He sets out some characters of the vibrio and shows that though it is normally a facultative anaerobe it is adaptable to strict aerobiosis during the phase of growth. He (p. 600) discusses the mechanism of the cholera red reaction especially as regards the part played by glucose: the discussion should be read in full.

GALLUT and GHARAR (p. 427) have previously demonstrated that the cholera toxin shows two fractions, one comprising a large molecule which is the O antigen, the other having a small molecule. They now show that the latter has no antigenic power.

Recognizing that the usual tests are not useful for differentiation of the true cholera and the El Tor vibrios, TANAKA (p. 706) has devised a serological test in which he uses the Damang O-antiserum (probably relating to Hikojima type vibrios) with a solution of sodium carbonate as diluent. At certain strengths of the sodium carbonate El Tor vibrios are agglutinated, but not *V. cholerae*. In another test without serum, but with sodium carbonate and mercuric chloride solutions, the cholera vibrios flocculate but the El Tor vibrios do not.

YU (p. 73) describes a modification of his phenolphthalein-starch medium for the isolation of *V. cholerae*. The new modification is a plate medium, and the vibrio grows in 18-24 hours and gives a clear greenish-yellow zone around the colonies. Other organisms tested did not give this zone or were inhibited by the malachite green and roxalic acid which the medium contains.

GOMAR (p. 690) describes two ingenious methods for isolating *V. cholerae*: detail are given in the abstract.

GOHAR and MAHRAWI (p 705) suggest the use of potassium tellurite, 1 in 50,000, in all-ahne peptone water for suppression of intestinal organisms which tend to overgrow the cholera vibrio. They have found it better than the other bacteriostatic substances examined.

Advice on the bacteriological diagnosis of cholera (on lines which have been noticed from time to time in this *Bulletin*) is given in a short article in the *Monthly Bulletin of the Ministry of Health and Public Health Laboratory Service* (p 336).

Immunity Studies

BURROWS *et al* (p 178) have been able to infect mice with cholera vibrios suspended in a solution of mucin, and have used this technique in a protection test of immune rabbit serum. Protective antibody may be in part anti-endotoxic, but is not necessarily identical with O agglutinin. There is little justification for drawing a close analogy between experimental infection and human cholera. [The paper should be read in full.] In a later contribution BURROWS *et al* (p 335) deal with the antibody found in the fluid faeces of infected guinea-pigs (coproantibody). This seems to be identical with serum antibody, though it is not clear how it appears in the faeces; it has agglutinative and protective properties. The authors discuss the difficult subjects of intoxication, infection and immunity which arise from their experimental work. In a subsequent paper BURROWS and HAYES (p 598) show that serum globulin is normally excreted in urine and faeces, and that immune globulin can either be absorbed or excreted through the intestinal wall. The presence of coproantibody in the faeces of immunized animals is related to these processes.

Clinical Findings

MARRIOTT (p 208) has greatly clarified the symptomatology of cholera by describing the effects of depletion of water and salt respectively. SAFWAT and ADHAM (p 898) refer to this in pointing out that cholera presents a combination of the picture of both. In water depletion there is thirst, diminished urine, no diminution of plasma volume, no reduction of blood chlorides, but in salt depletion there is no thirst, no reduction of urine (until late), great reduction of plasma volume and of blood and urinary chlorides. Treatment must take these facts into account. Haemoconcentration is an indication for 400 cc normal saline for each degree above S.G. 1060, but for simple water depletion only water is needed, by mouth. Acidosis may require intravenous 4 per cent sodium bicarbonate.

EL-RAWI (p 900) gives an account of the signs and symptoms of cholera as he saw them in a large number of cases in a fever hospital in Egypt. He found that 50, 91.7 and 100 per cent of carriers were free of vibrios in 5, 10 and 15 days respectively. There were 84 healthy carriers in 2,035 contacts, and contacts rarely developed the disease. He gave 400 ml of normal salt solution intravenously for each degree of blood specific gravity over 1050. Sulphonamides seemed to have no effect.

BURGH (p. 48) notes the complication he found in cholera in Egypt. The commonest was heart failure in the acute stage or even in convalescence. Suppression of urine was common before the routine of treatment was fully established. Abortion, pneumonia and other conditions are mentioned. A syndrome of transient paralysis complicating cholera, and possibly due to disturbance of potassium metabolism resulting from mobilization of barium from the bone reservoir in dehydration is described from China by HUANG and MUO (p. 75). It resembles a form of barium poisoning seen in China.

ANDOT (p. 85) thinks that cholera tend to attack person with achistosomiasis, ankylotomiasis, amebiasis and malaria rather than those free from these infection and bases his argument on his own observation in Egypt. He remarks that it was seldom that more than one case occurred in one family.

Treatment

CARRUT (p. 70) reports on the Swi. medical mission in Egypt which set up a hospital of 25 beds in the Delta. Treatment consisted of intravenous glucose-saline (5-10 litres in 4 hours), hypertonic saline sodium bicarbonate for acidosis and infusions of plasma for hypoproteinaemia. The case-mortality rate was 70 per cent. against 50 per cent. elsewhere. A very active phase was isolated and used to differentiate the Egyptian cholera strains from El Tor and non pathogenic vibrios.

GOODYEAR and BEARD (p. 120) describe the successful treatment of acute renal failure by peritoneal irrigation, and in comment on this paper MARGRAUS suggests that this procedure may have value in the renal failure of blackwater fever and cholera.

SEAL (p. 515) tested sulphaguanidine under field conditions in India, during a number of small outbreaks of cholera. The result showed that the death rate in the sulphaguanidine group was only 1.5 per cent., against 43.5 per cent. in the controls. Most of the patients in the two groups were not given any other effective treatment but a small number received saline. In spite of this and of the fact that the test was not done on an alternate case basis the results are decidedly in favour of sulphaguanidine, stocks of which could be kept in villages for use in outbreaks of this kind. In a small outbreak in Burma STERNITZ (p. 334) reports a death rate of only 4 per cent. as a result of early massive intravenous infusion of glucose-saline and treatment of milder cases with sulphaguanidine. He thinks that the vibrio may have been of low virulence and that preventive inoculation may have contributed to the low death rate. LAWRIE (p. 1000) in India found that both sulphadiazine and sulphaguanidine were valuable in cholera, to about the same extent.

On the other hand, LARSEN *et al.* (p. 515) conclude from good clinical evidence that sulphadiazine has no beneficial effect in cholera, but an extended test showed that sulphaguanidine has considerable value. PASRICHA *et al.* (p. 601) have not found any favourable influence on the death rate by treatment with sulphasuxidine or phthalyl sulphathiazole.

BEATYAGAR *et al.* (pp. 516-601) write most favourably of their experience with the compound of sulphathiazole with formalin (known as compound 6257), which they used in 83 patients with only 3 deaths. These patients were treated in their own homes and no other treatment was given. The drug was given to a total dose of 25-30 gm. in 7 days for a man. There were no toxic effects, and the beneficial effects were usually apparent in a few hours.

Control and Isolation

In the *Chron. of the World Health Organization* (p. 174) is an important declaration of international health policy in relation to cholera. It deals with isolation of patients and observation, contact, disposal of dejects, disinfection,

control of travel, vaccination etc It deprecates panic and the over-hasty closure of frontiers, and recommends surveillance for vaccinated travellers and surveillance with medical examination for those who have not been vaccinated

KOPANARIS (p 602) gives an account of the steps taken in Greece to prevent the introduction of cholera from Egypt Travellers from Egypt by sea and air were admitted at one seaport and one airport only, and were examined and if necessary detained Vaccine was used on a large scale and special attention was paid to persons who lived under unfavourable conditions—sewage workers etc No fresh food was allowed to be brought from Egypt, and mails were disinfected

STRAUSS (p 334) discusses the potential danger to Palestine of the Egyptian outbreak, and SILBERSTEIN (p 334) the technique of preventive inoculation of heat-killed vaccine

KHALIL Bey (p 704) discusses the Egyptian outbreak and the sanitary reforms necessary to prevent repetition A pure water supply from tube wells is needed in most of the villages

HALAWANI and OMAR (p 707) have found that copper sulphate, 20–45 p p m in Nile water, is lethal to *V cholerae* It is extensively used to eradicate snail hosts of schistosomes in Egypt, and it has its place in the prevention of cholera

Moving religious fairs have long been connected with cholera in India, but RAO (p 896) describes one in Hyderabad in which the incidence was very low, probably because nobody was allowed to join it who had not been vaccinated, and because the wells on the route were treated with permanganate or bleaching powder and great care was taken with the food provided in the villages for these pilgrims

ADISESHAN *et al* (p 336) review the results of inoculation with a single dose of 8,000 million *V cholerae* (mixed Inaba and Ogawa) in 118 million persons in 2,350 villages in India, and compare the cholera experience in these and in a large number of control villages Incidence rates were 10 and 14 times as high in control as in inoculated groups and villages, and the results appear to provide proof of definite protection On the other hand, an enquiry into the results of this vaccination campaign made by CHANDRA SEKAR (p 337) who took as his unit the compact block of a village, inhabited by the depressed classes, showed results which, though still favourable to inoculation, were less so than those quoted above. He found that the attack rate in the control population was 2–4 times as high as in the inoculated

GOHAR and MAKKAWI (p 706) show that nearly 20 million people were vaccinated during the outbreak in Egypt, mostly with one dose of 8,000 million organisms, they do not draw conclusions as to the value of vaccination GOHAR (p 901) has used an alum-precipitated cholera endotoxoid vaccine in Egypt, which he gave as a single intradermal dose in order to ensure slow absorption Details of preparation should be sought in the original GOHAR and ISA (p 1000) describe their animal experiments with 5 types of vaccines or toxoids from an Egyptian strain of *V cholerae* These showed some evidence in favour of a mixture of equal parts of toxoid and vaccine, and the authors give details of the preparation of an alum-precipitated toxoid vaccine mixture

KORDI (p 901) gained the impression, from a study of vaccinated and non-vaccinated patients admitted to his hospital in Egypt, that vaccination conferred a definite degree of protection and lowered the fatality rate

MALARIA

YACOB M & SWAROOFF S. Preliminary Forecasts of the Incidence of Malaria in the Punjab. *Indian J Malariology* 1947 Dec. v 1 No. 4 491-501 1 chart.

In thirty districts of the Punjab the annual incidence of malaria from 1914 to 1943 was correlated with the rainfall in each month of the year. In nineteen of them there was a fair degree of relationship between the rainfall in either March (two districts) April (three districts) or May (14 districts) and the subsequent epidemic incidence. For each of these districts the regression equations were computed for connecting malaria with the rainfall in the specified month. They were used to predict the malaria incidence in 1944 1945 and 1946 and these predictions could be compared with the actually observed epidemic figures. The degree of accuracy attained was measured by correlating the predicted figures with the observed figures, the coefficients being 0.25 in 1944 0.78 in 1945 and 0.55 in 1946. The low figure in 1944 was due to unusual floods and waterlogged areas in some districts. The other coefficients are statistically significant. The equation enable forecast to be made two or three months earlier than has previously been possible and are recommended as a method of estimating the epidemic incidence to be expected.

[The degree of a relation between prediction and the actual epidemic is not sufficiently close to make the method very reliable in individual districts as indeed the tabulated figures reveal. It is noticeable that almost all the predictions are too high and this clearly call for further study. It is of course presumed that the rainfall and the later malaria incidence are linearly related and only one month's rainfall has been utilized. A multiple regression or a curvilinear equation might improve the answer though the data given do not make it very hopeful.]

ZUJIGA, H & VIGILAN RIVAS A. Reconocimiento de malaria de la Ciudad de Santa Ana. Junio de 1946. [Malaria in Santa Ana, El Salvador.] *Bolet Sanitario* San Salvador 1946 Jan.-June v 4 No. 1/3 32-51 3 charts & 1 map.

The investigation the results of which are here reported, was undertaken in June 1946. The authors examined 1,134 persons, schoolchildren and others in the town, for splenic index and found 224 (19.7 per cent.) with enlargement. 661 were examined for parasites and 57 (8.6 per cent.) were positive, most with *P. falciparum* (74) next with *P. vivax* (13) *P. malariae* (4). 16 were not identified, there were no mixed infections recorded. Tables are given to show these indices in the 9 ward of the town. The splenic index was nearly the same in all, but the parasite index varied considerably and was highest in San Lorenzo, Santa Bárbara and Santa Lucía.

According to the statistical returns, malaria comes second or third among the causes of death in Santa Ana, the numbers in the quinquennium 1941-45 were 253 319 417 237 and 203 or per 10,000 inhabitants 24 35 45 24 and 21 respectively. The chief *Anopheles* present are *A. albanus* and *A. punctipennis* but the former only is said to be the malaria vector in the town.

H Harold Scott

CABALLERO A., with the technical assistance of C. G. DE PRATER. Mortalidad por malaria en Venezuela. I Bases estadísticas y distribución geográfica. [Malaria in Venezuela. Statistics and Geographical Distribution.] *Tratado Latinoamericano de Malaria* Venezuela 1946 Dec. v 10 No. 4 191-237 10 boxes.

The compilation of this paper (it is only the first of a series) must have entailed an enormous amount of work, but one is reminded of Tony Weiler's

pronouncement on his efforts to master the alphabet—whether it was worth while to go through so much to learn so little

The author has presented figures of the population, the births, the deaths from all causes and deaths from malaria and the rates of these for each of 36 years and for each of 21 States in Venezuela. There are seven line maps with shadings to show the mortality from malaria in the different States in successive quinquennia from 1910 to 1936. Much of the information is too detailed to be of more than local interest. Apart, however, from this, the figures as given lose much of their value because it is acknowledged that many births and deaths are not registered, so that the census is inaccurate, many deaths even when registered are not medically certified, there must be many cases of malaria not notified and, lastly, in many cases the cause of death is not known with certainty.

With these reservations in mind, serious as they are, but not the fault of, nor remediable by, the author, and not forgetting that fluctuations may be great from year to year, the States may be classified according to the malaria mortality into six groups: 1 Those with figures above 1,000 per 100,000—Anzoátegui, Carabobo, Cojedes. 2 Those with a rate of 750–1,000—Portuguesa. 3 With a rate of 500–750—Barinas, Guárico, Miranda, Monaga and Yaracuy. 4 With 250–500—Apure, Aragua, Falcón, Lara, Sucre and Zulia. 5 With 100–250—Bolívar, Trujillo and Trujillo. 6 Below 100—Mérida, Nueva Esparta and Distrito Federal. Speaking generally, malaria is worst on the plains then in order the valleys, the coastal districts and the south-east [but reference to the maps shows that there are exceptions to this].

PILLI F. & VAN HOOFF L. Comportement de *Plasmodium falciparum* dans le derme chez l'enfant indigène [Behaviour of *Plasmodium falciparum*, In the Skin of African Children] Ann Soc Belge de Med Trop 1948, June 30 v. 28 No 2 273-7

The intradermal juice of 50 African children suffering from *Plasmodium falciparum* malaria was examined. The ages of the children varied from four months to four years. The material was obtained by scarifying the skin, expressing the serum and making films from the first drops of the exudate. The parasites from the skin were compared with those in the peripheral blood and a striking difference was noted. In the blood, practically only ring stages were seen; in the skin growth proceeded much further and parasites in various stages of development were encountered. Solid pigmented parasites were common in the skin smears and there was nearly one mature schizont per field of the thin film. The actual number of parasites did not differ in the two situations and merozoites were present in both. The authors conclude that the skin is a normal site of schizogony of *P. falciparum* and they note that the p. c. in the skin resembles that of the placenta or deep organs. They failed to find any forms suggestive of exo-erythrocytic development.

P. C. C. Garman

stages of *Plasmodium vivax* in man [this Bulletin 1948, v. 45, 462]. In previous work on monkeys, SHORTT, GARNHAM and MALAMOS (ibid. 388) had found that it was necessary to induce very heavy infection by the bites of large numbers of mosquitoes infected with *P. cynomolgi* and by injection of sporozoites at the same time. If the pre-erythrocytic stages were to be found easily. A similar technique was used in the experiment in man and Shute gives in detail the technique adopted for raising the colony of some 10 000 *Anopheles maculipennis atroferrus* (*A. labranchius atroferrus* in the Bates classification) needed for the experiment and for infecting the required number on the donor patient. The volunteer recipient was bitten by 1510 mosquitoes on one day and by 500 the following day and the crushed salivary glands of 200 were injected intravenously. These glands probably contained 9,000,000 sporozoites.

Full details of the procedures adopted should be sought in the original paper. (The author is not accurate in describing the developmental cycle of *Hepatosystus kochi* (misprinted *kochi*) as the same as that of *P. cynomolgi*. The wording of one paragraph implies that pre-erythrocytic forms of *P. vivax* had previously been found in the livers of monkeys by Garnham and by Shortt and Garnham; this, of course, is incorrect. Garnham described the exoerythrocytic hepatic stage of development of *Hepatosystus kochi* in the monkey and Shortt, Garnham and Malamos the pre-erythrocytic stage of *P. cynomolgi* in the monkey. The slip is obviously unintentional, but an unconstructed reader might receive a wrong impression.)

DEL VECCHIO G. & DEL VECCHIO I. Prime osservazioni sull'anofelismo in provincia di Salerno. [Preliminary Observations on Malaria in the Province of Salerno.] Boll. Soc. Ital. Biol. Sper. 1948 Jan. F b v. 24, Nos. 1/2 7-8. [Summary taken from Rev. Applied Entom., Ser. B, 1948 July v. 39 Pl. 7 109.]

An Anopheline survey was carried out in 1943-45 in nine communes of the Province of Salerno in which malaria is endemic. Identification of eggs laid

which occurred along the coast where breeding places on high summer current were available.

OLIFAN V. I. Periodicity in the Postembryonic Development of *Anopheles maculipennis* C. R. (Dobzh.) Acad. Sci. U.R.S.S. Moscow 1947 v. 55 No. 2 169-77 2 figs. 12 refs. [Summary taken from Rev. Applied Entom., Ser. B, 1948 Aug. v. 39, Pl. 8, 140.]

Larvae of *Anopheles maculipennis* var. *parvus* Flu. and *atroferrus* van Thiel, were reared in tap water with yeast, infusoria and flagellates as food, and their respiration and rate of growth were observed. Measurement of the stigmatic and cutaneo branchial respiration with a micro-parameter gave the consumption of atmospheric oxygen and of that dissolved in water respectively. The changes in respiration that took place with the increasing age in one set of test are shown on a graph. It was found that respiration did not increase

steadily with the age of the larvae but showed a succession of increasingly high peaks separated by depressions. As a rule, the depressions more or less coincided with the moulting periods, and the peaks with the middle of each instar. In some of the experiments, however, a peak was preceded by a deep depression in addition to that occurring during the moulting period. There was a particularly high peak in the third instar.

The growth of the larvae was studied by measuring their length each day and computing the true growth-rate to obtain a graphic representation of the changes that took place with age. The resulting curve showed a succession of decreasing peaks, indicating that the increase in length of the larvae with age was of an intermittent character, growth was considerably slowed down soon after the beginning of the third instar owing to accelerated differentiation, and this instar was preceded by unusually high mortality.

It is concluded that there is a definite rhythm in the intensity of respiration and growth in the larvae of *A. maculipennis* corresponding to profound changes in their metabolism and that the intensification of growth at the beginning of the third instar and of oxygen consumption in the course of it is suggestive of the particular importance of that instar. The periodicity observed in growth and metabolism is thought to be controlled by the rate of production of hormones.

STEYN, J. J. The Effect on the Anopheline Fauna of Cultivation of Swamps in Kigezi District, Uganda. *East African Med J* 1946, June, v 23, No 6, 163-9.

Kigezi is a densely populated mountainous district in south-west Uganda. It lies at an altitude of 6,000 feet and has an average annual rainfall of 39.13 inches. Famine is apt to occur during drought years, consequently drainage of the papyrus swamps in the valleys was commenced in 1942 with the object of extending the area available for cultivation. A great increase in the incidence of malaria followed and investigations showed that the following anophelines were present: *Anopheles christyi*, *A. marshalli gibbinsi*, *A. costaini* and *A. demelloni*.

Previous workers had already shown that *A. christyi* was the commonest anopheline in African huts in the area and dissections produced an average gland infection for this species of 2.36 per cent with a maximum at one place of 4.1 per cent out of 98 females dissected.

The present author, therefore, in 1944-45, made weekly collections of anopheline larvae by a standard technique in five areas in which were sixty actual or potential breeding places in uncultivated swamp and eighty-seven in cultivated portions. He also made weekly collections of adults in twenty-four African huts. Results of adult catches are not given, but an analysis of 2,922 larval searches in untouched swamps and 5,886 searches in the cultivated portions is tabulated. The figures show that after cultivation there was a decrease in the numbers of *A. marshalli gibbinsi*, an increase in *A. costaini* and a much greater increase in the output of *A. christyi*.

Several breeding places of *A. christyi* are noted, but it is pointed out that it breeds particularly in cultivated ditches and disappears from them when they revert to swamp, also in water in paths through papyrus and where papyrus has been cut down, but as the papyrus begins to grow again the numbers of larvae fall. The number of favourable breeding places was also greater in cultivated than in uncultivated swamps.

The author concludes that as the cultivation of swamps as at present practised in Kigezi greatly increases the breeding of *A. christyi*, the increased incidence of malaria in this area is largely due to this cause.

GARNHAM P. C. C. WILSON D. Bagster & WILSON Margaret E. Malaria in Kigeri, Uganda. *J Trop Med. & Hyg.* 1948 Aug. v 51 No. 8 154-9

During a visit to Kigeri, in south-west Uganda, in September 1948 very high spleen rates were observed among all age groups of the population. A second visit was made in January 1947 to study this phenomenon and its relationship to *Anopheles christyi* recently recorded as a vector [above].

The area surveyed lies at an altitude of about 6,300 feet where the incidence of malaria had increased after intensive cultivation. Around Lake Banyonyi, the huts contained numerous *A. funestus* the dissected salivary glands of 275 females showed six with sporozoites (2% per cent) a few larvae of this anopheline were found among papyrus at the fringe of the lake. Huts in the Kigeri valleys where previous workers had found many *A. christyi* yielded only two specimens of this species and one *A. gambiae* one *A. funestus* nine *A. kingi* and three *A. marshalli* var *gibbatus*.

Spleen rates and parasite findings are tabulated and show that the spleen rates were high for such an altitude that the adult parasite rates were not very different from those in hyperendemic areas and that there was a high incidence of *Plasmodium malariae*.

The authors make some detailed suggestions, firstly for an investigation into the malaria situation to determine the part played in transmission by *A. christyi*, *A. gambiae* and *A. funestus* in such areas and secondly for certain experiments in anopheline and malaria control.

H. S. LERSON

GLAGOLEVA, E. M. [Ecological Studies on *Anopheles* Larvae in Tadzhikistan, Middle Asia. 2. Breeding Places of *Anopheles hyrcanus* Pall. and their Chemical Factors.] *Russ. Ent. URSS* 1947 v 29 No. 1 p. 109-18. [In Russian.] [Summary taken from *Russ. Applied Entom.* Ser. B 1945 July Pt 7 124.]

Anopheles hyrcanus Pall. is widely distributed and common in the lowlands in Central Asia. In Tadzhikistan it is abundant in low lying places in the valleys of the rivers Vakhsh, Kani-su and Ak-su and in the valleys of the Hindu Kush mountains its favourite breeding places being rice-fields and swamps fed by seepage from subsoil water lying close to the surface in which the water is slow moving heated by the sun and overgrown with floating and emergent vegetation and dense growths of reeds.

A study of the chemical composition of the water in typical breeding places was carried out in 1938-40 in rice-fields on four collective farms in three districts and a detailed account is given of the results. They showed that it was characterized by a low content of mineral (190-50 parts per million dry residue) a low degree of hardness a fairly high oxygen content (4.15-5.16 p.p.m.) a pH of 7.7-4 and a high temperature (30°C. [86°F.]) all typical of high-level subsoil water.

Larvae of *A. hyrcanus* unlike those of other species of *A. opheles* tolerate considerable quantities of both mineral and organic nitrogen and were not affected by about 4.34 p.p.m. nitrates in the water. In tests of various methods of reducing the mosquito population in rice-fields the introduction of organic fertilizers killed the larvae of all the species of *A. opheles* present except those of *A. hyrcanus*.

LERSON H. S. & THEODOR O. Mosquitoes of Socotra. *Bull. Entom. Res.* 1948 Aug. v 39 Pl. 2, 221-9 4 figs. (1 map) [15 refs.]

The paper contains an introductory account of the surface features and water supplies of the Island of Socotra. It seems that a fairly complete survey of

mosquitoes was carried out in the war period and that only two species of *Anopheles*, *A. dthali* var *wardi* and *A. culicifacies* var *adenensis*, were discovered. The former is here described as a new variety with an account of the adult male and female and of the structure of the larva. This insect is widely distributed in the island and occurs in water of many types. The following Culicines which might prove to be of some medical importance were found to be present: *Aedes vittatus*, *Culex fatigans* and *Culex sitiens*. *Aedes aegypti*, which had been recorded from Socotra years ago, was not encountered. The paper contains keys to adults and larvae.

DE BURCA, B & JACOB, V P Further Notes on Malaria in Fort Sandeman
Indian J Malariology 1947, Dec, v 1, No 4, 413-16

"In a survey carried out between mid-August and mid-October 1946 at Fort Sandeman, *A. stephensi* and *A. culicifacies* were found infected, gland infections in each case. No other mosquitoes occur in sufficient numbers to be of any practical importance.

"The Zhoob River was not considered to have any bearing on the malaria problem in this station during the period of the survey."

DE BURCA, B & FORSHAW, H W Winter Variations of the Larva of *A. fluviatilis* from Northern India and Bombay Presidency -*Indian J Malariology* 1947, Dec, v 1, No 4, 417-18

"A brief description is given of some winter variations noted in the larva of *A. fluviatilis* during the cold season of 1945-46 in North India (U P) and Bombay Presidency (Poona). A large proportion of larvae were found with branched outer or inner clypeals. A division of the outer clypeals with two equal branches was the commonest variation seen, and often this was unilateral."

SANDOSHAM, A A Identification of the Common Malayan Anophelines
25 pp, numerous illustrations 1945 Singapore

— The Identification of the Common Anophelines of Malai and Thailand
95 pp, 17 figs & 3 pls 1945 Singapore [Summary taken from *Rev Applied Entom* Ser B 1948, July, v 36, Pt 7, 112]

The first booklet comprises data on the morphology of the various stages of *Anopheles* in general and illustrated keys for the identification with simple equipment of the larvae and adults of both sexes of the 17 species of that genus that are common or important in Malaya, together with brief notes on their morphology, prevalence, biology and status as vectors of malaria there.

The second includes also most of the other information on *Anopheles* (except control measures) contained in the author's recent monograph on malaria in Malaya [this *Bulletin*, 1948, v 45, 1045] and in addition a list of the species and subspecies recorded in Siam and a summary of the available information on the morphology, prevalence, bionomics and status as vectors of malaria of ten species or subspecies common, widespread or important in Siam but not in Malaya. The keys to the larvae and females are amended to include these ten forms. The distribution of malaria and its probable vectors in Siam are discussed, mainly from the literature. Intense malaria in the hilly districts to the west of the central plain is associated with the breeding of *A. fluviatilis*, James, *A. culicifacies*, Giles, and *A. minimus*, Theo, and 14 or 15 other species occur in the area, including *A. barbumbrosus*, Strickl & Choudh, and *A. insulacflorum*, Sw & Sw, which are recorded from Siam for the first time.

doubtful value in diagnosis. While many observers think that a major operation or parturition may precipitate an attack of malaria, others doubt the importance of these factors.

The case histories of 1200 paretics treated in Amsterdam with induced malaria have been studied (almost all were apparently infected with *P. vivax* although one case of *P. malariae* is noted). This treatment aims to give the patient 10 or more pyrexial attacks but may fail because of an immunity from malaria previously accidentally acquired or arising from malaria therapy. During the course of infection with induced malaria, immunity may become so marked that after a few attacks the fever suddenly or gradually decreases and soon disappears altogether while in the blood parasites decrease or disappear completely. Inoculation with a different strain of *P. vivax* proved unsatisfactory in such cases and so did injections of adrenaline and application of artificial sunlight. Injections of milk, serum, pyril (bacterial proteins) dmelon (a suspension of *B. dysenteriae*) or sulpholine (a suspension of sulphur in oil) nearly always caused some degree of fever but even then had no influence on the number of parasites in the blood.

A summary of 24 paretic cases (one infected with *P. malariae*) whose immunity brought about a premature end to their treatment leads to the conclusion that if a patient develops resistance to malaria to such a degree that attack of fever ceases and parasites disappear nearly or completely provocative methods hardly ever succeed. Immunity often does not occur until the fever cure is interrupted by small doses (0.5 gm.) of quinine or benazaphenamine (0.15 to 0.3 gm.) according to the strain of *vivax* used.

The author concludes that once the infection has become latent in the patient's immunity it can rarely be activated by provocative measures within a reasonable time. In natural benign tertian malaria, approved provocative measures are far less important than is usually assumed. (In endemic areas there is always the difficulty if not impossibility of distinguishing between relapse and reinfection.)

JORDAN, W S, JR Primary Attack of Vivax Malaria occurring Twenty-seven Months after Infection *New England J of Med* 1948, Sept 9, v 239, No 11, 397-9 [16 refs]

This paper records the case of a United States ex-serviceman who developed an attack of *P vivax* malaria in Cleveland, Ohio, in December 1947. He had served in New Guinea and the Philippines from 1943-1945, he had never been in hospital, nor had he had any symptoms suggestive of malaria.

The author produces arguments in support of the proposition that this was a primary attack of malaria and he discusses the literature regarding delayed primary attacks and late relapses.

This patient had taken suppressive mepacrine daily until his return to the United States in September 1945. It is suggested that the drug was responsible for the delayed attack of malaria, which had occurred as long as 27 months after the patient's last known exposure in an endemic area. It is added that such prolonged latent periods have not been reported in natural malaria, and that symptoms of the disease usually appear much earlier after the discontinuance of suppressive mepacrine. The author points out that rare cases of malaria have apparently been acquired in Cleveland, and that there is a possibility that this patient had contracted the infection locally but against this were the time of year (December), the known exposure in an endemic area, and the presence of splenomegaly. *H J O'D Burke-Gaffney*

DELAHOUSSE, J Essai d'étude de l'activité thérapeutique de la Nivaquine (3038 RP) sur le paludisme à *Plasmodium falciparum* [Therapeutic Effect of Nivaquine (3038 RP) in *Plasmodium falciparum* Malaria] *Bull Méd de l'Afrique Occidentale Française* 1947, v 4, No 3, 203-6

The author refers to the work on Nivaquine in the prevention and treatment of malaria in North Africa by DECOURT and SCHNEIDER [this *Bulletin*, 1948, v 45, 148, 868]

The present experiments were carried out in Segou, French West Africa, and concerned the treatment with Nivaquine of 46 cases of subtertian malaria. The ages of the patients [presumably all Africans] varied from 7 months to 45 years. Two-thirds of those treated were children under 8 years. The author points out that the experiments were of limited value, as they were of short duration, the patients were not severely ill and only Nivaquine for oral administration was available.

Dosage was based on an adult dose of 0.3 gm daily, given in the morning in capsules containing 0.1 gm each. The temperatures and thick blood films were taken every 12 hours. The results of 46 patients so treated are shown in a table.

doubtful value in diagnosis. While many observers think that a major operation or parturition may precipitate an attack of malaria others doubt the importance of these factors.

The case histories of 1200 paretics treated in Amsterdam with induced malaria have been studied (almost all were apparently infected with *P. vivax* although one case of *P. malariae* is noted). This treatment aims to give the patient 10 or more pyrexial attacks but may fail because of an immunity from malaria previously accidentally acquired or arising from malaria therapy. During the course of infection with induced malaria, immunity may become so marked that after a few attacks the fever suddenly or gradually decreases and soon disappears altogether while in the blood parasites decrease or disappear completely. Inoculation with a different strain of *P. vivax* proved unsatisfactory in such cases and so did injections of adrenaline and application of artificial sunlight. Injections of milk serum pyrifex (bacterial proteins) dmelcos (a suspension of *B. dysenteriae*) or sulphosine (a suspension of sulphur in oil) nearly always caused some degree of fever but even then had no influence on the number of parasites in the blood.

A summary of 44 paretic cases (one infected with *P. malariae*) whose immunity brought about a premature end to their treatment leads to the conclusion that if a patient develops resistance to malaria to such a degree that attacks of fever cease and parasites disappear nearly or completely provocative methods hardly ever succeed. Immunity often does not occur until the fever cure is interrupted by small doses (0.5 gm.) of quinine or neocarphenamine (0.15 to 0.3 gm.) according to the strain of *vivax* used.

The author concludes that once the infection has become latent by the patient's immunity it can rarely be activated by provocative measures within a reasonable time. In natural benign tertian malaria supposed provocative measures are far less important than is usually assumed. [In endemic areas there is always the difficulty if not impossibility of distinguishing between relapse and reinfection.]

C. F. Sherrin

LIMBOS P. Présence de schizontes et de gamètes de *Plasmodium falciparum* dans le sang périphérique vingt-deux heures après la naissance. [Schizonts and Gametocytes of *Plasmodium falciparum* in the Peripheral Blood Twenty-two Hours after Birth.] *Ann. Soc. Belge de Méd. Trop.* 1948 June 30 v. 28 No. 2, 769-71.

A case of congenital malaria due to *Plasmodium falciparum* is described from the Belgian Congo. The mother, an African primipara, had suffered from two attacks of malaria during pregnancy and had another attack on the first day of the puerperium when scanty asexual forms of *P. falciparum* were found in a thick drop of blood. Labour was uneventful though the placenta was unusually friable and had numerous blackish haemorrhagic patches. Twenty-two hours after birth, the child had generalized convulsions; quinine was given by mouth for a week and no further symptoms developed. The child's blood (thick drop-) showed scanty asexual and sexual parasites of *P. falciparum* and in a thin smear the latter forms alone. This is claimed to be the first record of the discovery of gametocytes of *P. falciparum* in the blood of a child within twenty-four hours of birth. [These findings strongly suggest that intra-uterine malaria occurred, because gametocytes of this species of malaria are rarely found in infections younger than a week. Unfortunately neither the blood of the umbilical cord nor that of the placenta was examined.] P. C. C. Garnham

endemic or hyperendemic to demand control. The country falls into three natural types, in one of which there is little malaria, in another of which it is predominantly carried by *A. fluviatilis*, a notorious anthropophilic vector mainly breeding in streams and seepages, and in the third it is carried by *A. culicifacies*, a more omnivorous species commonly associated with pools.

Much experimental work has been done in this district and malaria control by prevention of breeding has proved impossible at the cost which could be envisaged. DDT residual spraying was started in 1946-47. The dosage applied is 56 mgm DDT per square foot (2 oz per 1,000 square feet) in the form of a soap emulsion in water of a concentrated solution of DDT in medium kerosene extract, a petroleum fraction with a high aromatic content. In the areas affected by *A. culicifacies* applications were made, at intervals of six weeks, to all human and animal shelters up to ceiling height or the maximum reach of the operator. In those affected by *A. fluviatilis*, applications were made at intervals of two months to human and mixed habitations only up to a height of 10 feet. The cost of treatment worked out at two annas (2 7 pence) per person protected per round, or six annas (8 1 pence) per year.

The results have only been followed for one year. In the areas affected by *A. fluviatilis* where some previous control by other means had been carried out the spleen rate has dropped from 72.2 per cent to 14.4 per cent, and the parasite rate from 14.6 per cent to 3.5 per cent. In those affected by *A. culicifacies* where there had been no previous control the drop in the spleen rate is from 28.3 to 19.6 per cent and in the parasite rate from 7.5 to 4.4 per cent.

In both areas an effort was made to estimate the infant parasite rate, but controls were difficult as villages were only left unsprayed either because they were non-malarious or because they were very small and inaccessible. In the *culicifacies* area, no infections were found among 237 children examined, and in the *fluviatilis* area three were found among 367 children. For the reasons stated, the controls also showed very low figures of 2.1 per cent and 13.33 per cent.

AFRIDI, M. K. & SINGH, D. A Scheme for the Control of Malaria in Villages in Delhi Province. *Indian J. Malaria* 1947, Dec, v 1, No 4, 423-40, 2 maps.

This paper gives a description of the organization but not the results of malaria control by residual DDT spraying in the villages of Delhi Province, which have a population of 292,102 subject in varying degrees to epidemic malaria at the height of the summer. Many surveys and many schemes of control have been carried out before, the most hopeful being by pyrethrum spraying. Under the new organization staff is more elastic than before. DDT is applied in a number of forms and doses varying from 50 mgm per square foot (2 oz per 1,000 sq ft) as a suspension, to 10 mgm (0.4 oz per 1,000 sq ft) as an emulsion. Two applications at intervals of six weeks are given to places where the spleen rate exceeds 20 per cent, and one application to places with spleen rates between 5 and 20 per cent. The estimated annual cost per caput works out at 7.8 annas (10.4 pence).

RAO, V. V. & RAMAKRISHNA, V. Control of Breeding of *A. sundaus* by *Eichhornia* Cover. *Indian J. Malaria* 1947, Dec, v 1, No 4, 419-21.

"In Orissa Coast, the presence of *Eichhornia speciosa* does not inhibit the growth of other aquatic vegetation nor does it prevent the breeding of *A. sundaus*. The experiences are at variance with the observations made in Bengal." [See also this *Bulletin*, 1947, v 44, 564.]

Only one complete failure was recorded, that of a child of 7 years in whom schizonts persisted after 5 days of treatment. One child of 6 years relapsed after 4 weeks. Otherwise results were very satisfactory: temperatures returned to normal in an average of 30 to 36 hours, that is after the second dose and parasites disappeared from the peripheral blood in 30 to 60 hours after the third dose. No toxic effects were noted. The drug had no effect on gametocytes and required to be supplemented with rhodopraequine (re-embling plasmoquine). The treatment had little effect on splenomegaly.

The author thinks as a result of these experiments, that Nivaquine is almost equally as effective as mepracrine when given by the mouth. It has the advantages of low toxicity, of being colourless and of being put up conveniently in capsules.

AZIZ, M. Interim Report on Island-Wide Anopheles (Malaria) Eradication Programme for the Year 1947. *Cyprus Ann Med & Soc. Rep 1947* Appendix F pp. 18-32, 11 graphs & 1 map

The campaign for eradication of mosquitoes from Cyprus was begun in 1946 and the results of the first year's work are described in earlier papers [this Bulletin 1948, v 45 157]. The work in 1947 was extended to cover more than half the island including an area of about 2,000 square miles. The same methods were used but the staff had to be expanded from about 100 to over 400 to cope with the increased area. About 7½ tons of DDT dissolved in 270 ton of gas oil were used. Total expenditure amounted to about £75 000.

As the work proceeded through the year a greater and greater proportion of blocks in the eradication area were found negative for anophelines, whereas in the western end of the island in which merely regular control measures were maintained, a very high proportion of areas were positive. The checking of breeding and resting places was maintained in the Karpas peninsula (1946 eradication area). This remained nearly free throughout the year though a few blocks were reported positive in August.

As a result of the eradication scheme the malaria incidence as reflected in new acute cases, in blood and spleen indices has been brought almost to extinction in the eradication areas. It is however shown that there has been a gradual decline in malaria since 1944 even in the "control" area of the island.

VISHWANATHAN D K. & RAMACHANDRA RAO T. Control of Rural Malaria with D.D.T. Indoor Residual Spraying in Kanara and Dharwar Districts, Bombay Province. First Year's Results. *Indian J Malariology* 1947 Dec., 1 No 4 503-42, 1 map & 3 chart (2 folding) (13 refs.)

This paper should be consulted in the original by all concerned in malaria control by DDT residual spray in the Eastern hemisphere. It constitutes a report on the largest successful scheme yet undertaken by the world. Work is being done in the districts of Bombay Province with a total population of 1,642,173 of whom 723,174 lived in places where malaria was sufficiently

It will be remembered that if one puts a male and virgin female of different species or sub-species of tsetse in a cage, complete failure to mate may occur. But in many cases, the insects pair though the female does not produce larvae occasionally hybrid offspring are produced which are nearly always sterile. A female which has paired with a "different" male cannot subsequently mate with a male of her own species and is in fact sterilized.

The paper sets out the results of more than a hundred types of crossing which involve the use of twelve species of *Glossina* and over three thousand individuals. Failure to produce living issue is due to a variety of causes, among them mechanical difficulties in pairing, failure in fertilization of the eggs, failure of the larva to develop, and so forth. The author makes use of a number of ingenious techniques. He says that individuals of two species will not mate unless the right musical note which comes from the wing beats of the female is produced; apparently it is possible to produce the correct note mechanically, and this is followed by pairings which would not otherwise occur. He has been able to remove eggs from a virgin female, mix them with sperm and incubate them on agar. If the parents are of the same species or sub-species, eggs will develop to the hatching stage in 100 per cent of cases.

In nature the range of certain related species overlaps: this is true for instance of *swynnertoni* and *morsitans* in a few places, and it is known that in the laboratory cross-pairing between them occurs readily with an effective sterilization of the female. In some of these areas aberrant adult tsetse have been taken which are probably natural hybrids. The author suggests that *Glossina newsteadi* may perhaps not be a species in the accepted sense of the word, but a naturally occurring hybrid between *G. caliginea* and either *pallicera* or *palpalis*. He discusses the status of sub-species in *Glossina* and the general relation of the three groups which are recognized in the genus to one another. The paper is of considerable interest to geneticists. P. A. Buxton

VILAIN, P. Note sur l'application du "Sélective Clearing" dans la région de Gaoua (Secteur spécial No 9) [The Use of "Selective Clearing" in the Gaoua Region] *Bull. Méd. de l'Afrique Occidentale Française* 1947, v 4, No 3, 289-91.

The paper describes the use of "selective clearing" against *Glossina palpalis* in the Gaoua region, Upper Volta Province, French West Africa. The author has received much help from MORRIS, whose work on similar problems in the Northern Territories of the Gold Coast is familiar [this *Bulletin*, 1946, v 43, 537-1947 v 44, 51]. Fly is confined to narrow riverside belts, in which contact with man is close, as people live on the waterside. By destroying certain types of waterside bushes and trees, tsetse may be exterminated. It seems that no great amount of clearing has yet been carried out. The cost is five to six thousand francs per kilometre, to include both banks of a stream.

TRYPANOSOMIASIS

PACKCHANIAN A. The Fate of some Pathogenic Trypanosomes in *Triatoma* and *Ornithodoros*. Amer J Trop Med 1948 July v 28 No. 4 541-3

"1. *Trypanosoma brucei*, *T. gambiense* and *T. hippocampi* survived only four to six days in *Triatoma*. The majority of the flagellates were found dead after two to four days. At the end of ten days no flagellates were found viable by either microscopic examination or animal inoculation test.

2. *T. brucei*, *T. gambiense* and *T. rhodesiense* likewise failed to multiply in soft ticks (*Ornithodoros turicata*). The flagellates remained viable from two to four day but at the end of ten days all trypanosomes were found dead or disintegrated. The animal inoculation tests were likewise negative for seven days and after.

3. It is concluded that neither *Triatoma* nor *Ornithodoros* will play any major role in the transmission of African sleeping sickness, nagana, or surra."

VANDERPLANK F. L. Experiments in Cross-Breeding Tsetse-Flies (*Glossina* Species). Ann. Trop. Med. & Parasit. 1948, Sept., v 42, No 2, 131-52 2 figs. [25 refs.]

The author has carried out a large amount of work on cross-breeding between different species and sub-species of *Glossina*. The paper does not deal with the possible use of this method for controlling *Glossina* in the field (see this Bulletin 1948 v 45 51)

Some practical tests were done in infested cellars. These were sprayed with gamma BHC and observed to note number of dead bugs appearing in subsequent periods. The final numbers alive were assessed after spraying with "Fly Tox", a pyrethrum spray which drives out the hiding bugs. Fairly good results were obtained if about 1 gm gamma BHC was applied per square metre. Better results were obtained with a combined gamma BHC plus pyrethrum spray which secured a good initial kill.

A trial of three gamma BHC smoke generators (56 gm BHC containing 10 per cent gamma) in a 40-cubic metre infested cellar, were disappointing, many triatomas survived.

CORKILL, N. L. Activation of Latent Kala-Azar and Malaria by Battle Experience. *Ann Trop Med & Parasit* 1948, Sept, v 42, No 2, 224-9, 1 map & 2 graphs

A military unit ["a company", number unspecified] was recruited in June 1940 in the Nuba Mountain area of the Sudan, where leishmaniasis is very rare, the men therefore were presumably not infected with, but were susceptible to, kala azar. The unit was moved to Southern Fung, an area of high kala azar endemicity, in October, 1940, one man was there hospitalized for an undetermined condition, at post mortem 104 days later he was found to be suffering from kala azar. It is suggested that he acquired his infection in the hospital, local cases of kala azar being concurrently treated there. In

OSIMAKI J. J. Resultados obtenidos con el uso de la fijación del complemento en el diagnóstico de la enfermedad de Chagas. [Complement Fixation in Chagas's Disease.] *Arch. Uruguayos de Med. Ciruj. y Especialidades* 1947 Sept., v. 31 No. 3 123-54. [Bibliography] English summary

For antigen the author used extracts of the spleen of a dog infected with *T. cruzi*. He prepared 21 stocks of "moist antigen" obtained by macerating the spleen in water with one-third glycerin and a small quantity of phenol and 15 stocks of "dry antigen" by triturating ~~in vacuo~~ at low temperatures. [Details of the preparation are not given in this paper. It is stated that methods of preparation and technique of the test are described elsewhere.]

In all 463 sera were tested. 330 from healthy subjects or those suffering from diseases other than Chagas's disease. 100 syphilitics giving a positive Wassermann reaction and 43 with Chagas's disease proved by blood examination or by xenodiagnosis.

Cases of the disease are subdivided into three groups. 1. Those with fever, adenopathy and splenomegaly—the acute initial stage of the infection usually on the 18th or subsequent days. 2. The latent period—a not very definite period between the acute early stage and the later tertiary stage. It corresponds to what has been called the subacute form of the disease. 3. The tertiary period with cardiac changes—the chronic form of the disease.

Of 13 in the first and early second stages, i.e. within a year of onset tested with the moist antigen 12 were positive and of 10 tested with the dry antigen 7 were positive. Seven were tried with both antigens and, with one exception, the results were identical. This one gave a one-plus with the dry and two-plus with the moist antigen. Of 19 of the chronic cases group tested with the moist antigen 10 were positive. Of 23 tested with the dry antigen 13 were positive altogether of 32 different patients 18 or exactly half were positive. Twelve were tested with both antigens and, as with the first group, all but one gave the same results with both—the exception, as in the one in the first group gave a one-plus with the dry and a two-plus with the moist antigen.

In the primary stages the W. R. may be positive without the presence of syphilis but as the acute symptoms subside the W. R. becomes negative.

H. Harold Scott

DIAS E. & PELLEGRINO J. Alguns ensaios com o "Gammexane" no combate aos transmissores da doença de Chagas. [Experiments with Gammexane against Vectors of Chagas's Disease.] *Brasil-Médico* 1948 May 1 8 & 15 v. 62 Nos. 18-19-20 185-91

Experiments were carried out with preparations of gamma BHC to determine the effectiveness of this insecticide for controlling *Triatoma* (*T. infestans*) the carrier of Chagas's disease. Laboratory tests were made with dried mud or wood surfaces, the former being similar to cellars which the triatoma infest. Such surfaces rapidly absorb sprays and it was necessary to employ a preparation of gamma BHC which was deposited superficially. A satisfactory product was found in "Gammexane" P530 which forms aqueous emulsions. Dried mud surfaces treated with 1.2 gm. of gamma BHC per square metre were lethal to adults and nymphs of *T. infestans* after a minute's contact. A surface of mixed mud and straw required rather longer (3-15 minutes' contact).

Adults were more susceptible than nymphs. Test repeated later showed that the toxicity had greatly declined after a month and even more after two months when exposures of several hours did not always kill. Gamma BHC was superior to DDT in these tests.

Many of the recent observers of the typhus fevers have tended to ignore the evidence that can be obtained by a study of the epidemiological conditions associated with outbreaks]

John W D Megaw

RIVOALEN, A Considérations épidémiologiques et biologiques à propos d'une épidémie de typhus au Tonkin (1944) [Epidemiological and Biological Considerations connected with an Epidemic of Typhus Fever at Tonking (1944)] *Bull Soc Path Exot* 1948, v 41, Nos 5/6, 329-33

Two exceptionally large epidemics of typhus fever in Indo-China are described. Between August 1943, and March 1944, there were 352 cases in South Annam, the mortality rate was 17.6 per cent. Between February and June 1944, 726 cases were admitted to a hospital in Tonking, it was estimated that between four and five thousand cases occurred in Hanoi and its suburbs, and tens of thousands in the delta.

Rickettsiae isolated in the South Annam epidemic caused a slight scrotal reaction in three out of fifty inoculated guinea-pigs.

The mortality rate in the Tonking hospital was 16.6 per cent in February, but it gradually fell and was only 6.9 per cent in June. Scrotal reactions are said to have occurred rather frequently ("*assez fréquemment*") among the guinea-pigs inoculated at the Hanoi Pasteur Institute.

Detailed laboratory studies were impossible at the time, but three years later the serum of a former patient (the author himself) was found by Giroud to have more active antibodies against epidemic than against murine typhus when tested by the rabbit dermal reaction.

In the discussion following the reading of the paper, GIROUD reiterated his opinion that it is difficult to differentiate epidemic typhus from murine typhus by animal inoculation, he mentioned his own experience of finding that epidemic rickettsiae sometimes caused scrotal reactions and that murine rickettsiae might, or might not, be fatal to mice.

[There seems to be little doubt that the epidemics were of louse-borne typhus. The author considers the fatality rate to have been lower than would have been expected in epidemic typhus, especially as only the more severe cases were likely to have been sent to hospital, but the louse-borne disease tends to be less virulent in hot climates, where for some reason transmission of infection does not readily occur.]

John W D Megaw

EVANS, A S Observations on Typhus in Okayama, Japan. *Bull U S Army Med Dept* 1948, Sept, v 8, No 9, 733-41, 2 figs [22 refs]

Between February and July 1946, 184 cases of typhus fever were reported in Okayama Prefecture. The outbreak was part of a widespread epidemic of louse-borne typhus in Japan and Korea during "the latter part of 1945 and extending through the first six months of 1946". It was estimated that 30,000 cases had occurred and that the case fatality rate had been 6-10 per cent in the epidemic as a whole.

Murine typhus is believed to be endemic in Okayama, and the local physicians classed 56 of the 184 cases as murine on clinical and epidemiological evidence which the author regards as quite unreliable. The information obtained in connexion with the louse-borne cases points to a close resemblance between the disease and the epidemics occurring in other parts of the world.

John W D Megaw

May 1941 the men were engaged in battle under arduous climatic conditions. Immediately afterwards cases of fever due to kala azar were found among them—their appearance bore no relation to the local seasonal peak of incidence of the disease. The unit, in November 1941 was again engaged in battle in the same place under similar conditions, and further cases of fever due to kala azar followed. The appearance of all recorded cases is depicted diagrammatically—it would appear that the total number was 24.

The onset of relapses, or of delayed primary attacks, of malaria in European troops as a result of battle experience suggested itself as a comparable phenomenon. A study of hospital records of such cases in 1944 supported this view and in a graph is recorded the incidence of such attacks of malaria in British troops following the invasion of Europe. The peak of incidence among these considerably antedated that of the normal seasonal relapse wave which, in them, when it occurred was consequently largely abortive. It is suggested that the activation of both the kala azar and the malaria infections was due to increased adrenaline secretion resultant on emotional stress.

CORKILL, V. L. Activation of Latent Kala Azar by Malaria and Relapsing Fever. *Ann Trop Med & Parasit.* 1945 Sept. v 42, No. 2, 230-35
1 graph.

The peaks of admission to hospital of kala azar and of malaria in the Sudan, as in India and elsewhere, tend to be associated. These normally occur in the Sudan in the latter part of the year. In 1940 at Gedaref in the Sudan an abnormal rise in the incidence of detected cases of kala azar occurred in the spring. This was found to be associated with an outbreak of relapsing fever. The rise in incidence usually taking place in the latter part of the year was largely abortive on this occasion. Data showing the reported incidence of cases of malaria, of kala azar and of relapsing fever and their association are set forth in graphs.

FEVERS OF THE TYPHUS GROUP

JADIN, J. Le typhus exanthématique de l'Urundi. [The Exanthematic Typhus Fever of Urundi.] *A. n. Soc. Belge de Méd Trop.* 1945 June 30 v 28 No. 2, 189-211, 2 charts & 1 map.

The author and P. GIBERT have already reported that in the 1945-1946 epidemic of typhus fever in Urundi the rickettsia-agglutination reaction was of the epidemic type [see this *Bulletin* 1945 v 45 582]. In the present paper a detailed study of strains of rickettsiae isolated from patients during the epidemic is described. A pericrathic reaction occasionally severe was often caused in guinea-pigs, but the results of complement fixation and rickettsia-agglutination tests carried out on patients and inoculated animals pointed definitely to *Rickettsia prowazekii* as the cause of the epidemic. Lighter samples of serum from patients were sent to the late Harry Plotz who reported that 13 of them gave complement-fixation reactions typical of epidemic typhus.

These findings disagree with those of NEUFJAN who maintained that the previous epidemics in the same region in 1893-34 and 1899-40 were caused by murine rickettsiae [*Ibid* 1946, v 43 324].

The scanty information supplied with regard to the epidemiological and clinical features of the epidemics points rather strongly to house-borne infection.

Lanchow, China High, or moderately high, titres were reached with both tests in 72.7 per cent of the cases such titres were reached with the Weil-Felix test alone in 9.1 per cent and with the complement-fixation alone in 18.2 per cent of the cases. The time of appearance of the antibodies was variable, sometimes one of the tests became positive first, sometimes the other. In some cases the earliest positive result with either test was delayed till the 12th or even the 14th day.

Among bacteriologically proved cases of enteric fever in Peiping, the Weil-Felix test became strongly positive in two, and a mixed infection was suspected, a rise of the titre to 1-80 or 1-160 was observed in 10 other cases.

Among 67 cases of fevers other than typhus, 10 showed a rise in titre with the Weil-Felix or complement-fixation test, in two of these both reactions became strongly positive and a dual infection was suspected, in one the Weil-Felix reaction was positive 1-80, and there was no rise in the complement fixation titre, in the remaining seven cases the fixation titre rose to 1-8 to 1-64 and there was no rise in the Weil-Felix titre.

The authors suggest that "a small rise in titre of either antibody itself does not constitute a diagnostic criterion" but should be evaluated in correlation with the clinical evidence.

D'ICNAZIO, C & CODIFLEONCINI, E La reazione di Weigl nella diagnosi precoce e precocissima del tifo esantematico [The Weigl Reaction in the Early and Earliest Diagnosis of Typhus Exanthematicus] *Acta Med Italica* 1948, Aug, v 3, No 8, 208-12, 1 chart English summary (7 lines)

The authors claim to be able to make a very early diagnosis of typhus fever by employing Weigl's micro agglutination reaction in which suspensions of *Rickettsia prowazekii* are used. The special features of their technique are the employment of very low dilutions and the repetition of the test every four hours. The series of dilutions starts at 1-3 and rises by slow degrees to 1-6, 1-9, 1-12, etc.

Among 13 patients tested on the first day there were already five positive reactions at a titre of 1-3, among 27 tested on the second day there were 18 positives, including one at a titre of 1-18, five at 1-12, and seven at 1-9.

The reaction is said to become positive one to one and a half days earlier than the Weil-Felix test, but in the latter the lowest dilution employed was 1-20 so that the conditions were not comparable. The special interest of the study is that it suggests the possibility of detecting the earliest rise in the agglutination titres by repeated tests with low dilutions of the sera.

BALTAZARD, M & BAHMANIAR, M Presence du virus du typhus murin chez les rats des ports d'Abadan et Bender-Bouchir (Golfe Persique) [Murine-Typhus Infection among the Rats of the Ports of Abadan and Bander-Bouchir (Persian Gulf)] *Bull Soc Path Exot* 1948, v 41, Nos 5/6, 174-5

At Abadan in South Iran the authors trapped 49 rats of which 19 were *Rattus norvegicus*, 13 were *R. alexandrinus*, and 17 were *R. frugivorus*. An orchitic strain of rickettsia was isolated from a pool of three *R. norvegicus*, and another strain from a pool of three *R. alexandrinus*.

At Bouchir 66 *R. frugivorus* and 6 *R. norvegicus* were caught. *R. alexandrinus* was absent. An orchitic strain was isolated from a pool of four *R. norvegicus*. No infection was found among rats of the species *R. frugivorus*, the indigenous

PÉREZ GALLARDO F & FOX, J P Infection and Immunization of Laboratory Animals with *Rickettsia prowazekii* of Reduced Pathogenicity Strain E. *Am J Hyg* 1948 July v 48, No. 1 6-21 [29 refs.]

This is a study of strain E (E for *Espana*) of *Rickettsia prowazekii* isolated in Madrid in 1941 by CLAVERO and GALLARDO and found to be of persistently low virulence to man and animals while being of good potency as an immunizing agent (see this *Bulletin* 1944 v 41 24 and 1945 v 42 794)

The strain has now been maintained through 255 egg passages and taken to New York for the further studies described in the present paper

The strain has been found less pathogenic than other epidemic strains for mice eastern cotton rats rabbits and guinea-pigs it could not be established in guinea-pigs but has been maintained without any change in pathogenicity through 11 passages in cotton rats It has also been passaged once or twice through lice.

The immunity caused in animals by inoculation with the strain was weaker than that caused by other strains of *R. prowazekii* but was enough to protect cotton rats and guinea-pigs against relatively large challenge doses of virulent epidemic and murine rickettsiae.

Sera of infected guinea-pigs fixed complement at titres lower than those observed after infection with other strains, and it was found that the titre of the reaction varied according to the size of the infecting dose of rickettsiae, whereas a variation of this kind is not observed with virulent strains.

The value of the strain as a living vaccine for human beings remains to be tested but trials are regarded as justified in view of the existence of a potent therapeutic agent para-aminobenzoic acid.

GIROUD P & JEJERSKI A. Pouvoir toxique des rickettsies du typhus épidémique ou rennin provenant de passages pulmonaires. Différenciation des souches. (The Potency of the Toxins of Epidemic and Murine Typhus *Rickettsiae* obtained by Passage through Lungs. Differentiation of Strains.) *Bull Soc Path Exot* 1949 v 41 Nos. 5/6, 336-8.

The experiments described were devised with a view to finding whether the toxicity of epidemic typhus rickettsiae would be modified by repeated passages through lungs.

Comparison was made between epidemic rickettsiae which had been maintained by rabbit-lung passage for six years and a strain of murine rickettsiae of which no details are given except that it was of pulmonary origin.

Injections of rickettsial suspensions were given by the intraperitoneal, intravenous and intracerebral routes to white mice of which 250 were used. The intravenous route was found most suitable for estimating the toxicity of the strains but by all three routes the epidemic strain was less toxic than the murine. By the cerebral route the murine strain caused paralysis in mice whereas the epidemic strain caused no manifestations of this kind.

LEE Wen-wing, CHANG, Hwei-ching & WANG Pei-chen. Frequency Concentration and Behavior of *Proteus vulgaris* O/19 Agglutinin and Complement Fixing Antibody for *Rickettsia prowazekii* in Typhus and Non-Typhus Febrile Patients and in Normal and Vaccinated Persons. *Chinese Med J Shanghai* 1949, Apr v 68 No 4 177-81 [23 refs.]

This paper contains an account of a detailed study of the Weil-Felix and complement fixation reactions observed in 33 cases of house-borne typhus in

sputum of German soldiers. One of these strains was maintained through 20 guineapig passages over a period of 15 months, and was identified early in 1945 in America as *Rickettsia burneti* by DINGLE to whom the strain was submitted.

In the further studies described in the present paper, complement-fixation tests revealed the occurrence of inapparent infection among physicians and other persons who had come into close contact with patients, and also the occurrence of infection among goats in Greece and Asia Minor.

Kids and lambs were experimentally infected by nasal instillation or subcutaneous inoculation of infected blood, after an incubation period of 6-10 days there was a febrile attack lasting 7-12 days, and the blood of the animals was found infective during the whole febrile period.

Horses and mules were found to be highly susceptible to subcutaneous inoculation, dogs were somewhat susceptible, but cats were resistant.

Goats and sheep, inoculated by the nasal route with the blood of infected guineapigs, developed severe attacks in which bronchopneumonia was a pronounced feature. The milk of infected goats remained infective throughout the rest of the period of lactation and samples kept in the refrigerator remained virulent for at least three months.

In Athens the milk of a flock of 16 Maltese goats was examined in pools, and it was found that at least four of the animals were infected. Other flocks of goats yielded similar results.

Nine new-born kids and five new-born lambs of infected mothers were found free from infection at birth, but 8-10 days later they had febrile attacks and *R. burneti* was isolated from their blood. The above observations are regarded as showing that milk is the source of natural infection among animals and that it "must be also the source of human infection". The author states that although transmission in man can occur by the inhalation of particles of sputum, this does not appear to be the chief natural mode of spread of infection, because the seasonal arrest of the disease in summer is correlated with the cessation of lactation among goats and sheep.

The author seems to suggest that the mechanism of transmission by milk is through direct contact of the milk with the upper air passages, he states that this mechanism would help to explain the special involvement of the respiratory system in man and lower animals.

[In their study of 117 cases of the disease in Southern California HUEBNER *et al* found no evidence that infection was transmitted to man by drinking milk, though they thought it possible that milk might be a source of infection by some mode not yet determined (see this *Bulletin*, 1948, v 45, 509).]

IMHAUSER, K. Untersuchungen über den Erreger der "Viruspneumonie" [On the Aetiology of "Viruspneumonia"] *Klin Woch* 1948, June 1, v 26, Nos 21/22, 337-9 [15 refs]

The paper recounts experiments on guineapigs and rabbits inoculated with sputum from cases of epidemic bronchopneumonia seen in Greece and South-East Europe in 1941 and 1944.

The treatment was started on the 3rd to the 11th day of the fever (average 6.2 days). The duration of the fever after treatment was started was 10 to 94 hours (average 31 hours). The treated patients were discharged from hospital 9 to 28 days (average 19.5) after the onset of the illness the control patients were discharged 17 to 53 days after the onset (average 30.7 days).

There was no death and no complication among the treated, one of the control patients died and two had complications, parotitis and pneumonia, respectively.

The remarkable response usually shown to the drug is shown by the chart of a typical case.

Typical response of patient with scrub typhus
Following treatment with chloramphenicol
[Reproduced from *Science*]

In the earlier cases the treatment was on the lines recommended in the previous paper but the course was gradually shortened and the last seven patients received the drug for only 24 hours during which time a total quantity of about 6.0 gm. was given.

PLAGUE

DAVIS, D H S Sylvatic Plague in South Africa History of Plague in Man, 1919-43 *Ann Trop Med & Parasit* 1948, Sept, v 42, No 2, 207-17, 5 figs & 1 diagram

This paper is the first part of a study of human plague of sylvatic origin in the Union of South Africa. It describes the spread of the disease from 1919 to 1943, the next paper will deal with the ecological factors concerned in the spread. Until 1912, plague was of domestic rodent origin and occurred solely in towns. Then followed a series of outbreaks on remote farms in the Cape Midlands which were proved to be of sylvatic origin. Farm workers were the chief sufferers, they contract the disease in huts and outbuildings where the domestic rodents have become secondarily infected from the gerbils. The gerbils (*Ialaca brantsii* and *schinzii* in the high veld and *Desmodillus auricularis* in the karoo) form the chief primary reservoir, these animals infect the semi domestic *Mastomys natalensis*, which infects in its turn either man directly or man via the intermediary of the domestic *Rattus*. If the chain of infection reached urban areas, serious epidemics might be expected but curiously enough have rarely actually occurred. Instead, there have been over 900 outbreaks in rural areas which have usually been the pointer to the existence of preceding epizootics amongst the wild rodents. There were two major epidemic periods, (1) between 1923 and 1925 and (2) between 1934 and 1936, with the incidence rising to smaller peaks every 5-6 years. The initial foci were in the North Western Orange Free State, in the Cape Midlands in the Southern Transvaal (near Johannesburg) and in the Uitenhage District. Between 1925 and 1931 there was a westerly expansion throughout the karoo and the Kalahari Desert which carried the infection into South-West Africa and Bechuanaland. During the next six years (up to 1937) epidemics occurred throughout the Orange Free State and infection spread into Angola, Basutoland and into the Rhodesias. As far as the Union was concerned, enzootic plague had reached its limits by 1937, and the situation has remained static except for three hyperenzootic areas—Northern Orange Free State, a small focus in the Cape Midlands and in Uitenhage. Sylvatic plague flourishes today among the burrowing rodents of the rolling semi-desert country, it is absent in North Eastern Transvaal, Natal and the coastal and low-lying parts of the Cape Province.

BUXTON, P A Experiments with Mice and Fleas I The Baby Mouse *Parasitology* 1948, July, v 39, Nos 1/2, 119-24, 2 figs

During investigations into the feeding habits of the flea *Xenopsylla cheopis*, it was frequently observed that adult mice, when used as hosts in laboratory experiments and in stock cultures, ate a number of the fleas. When baby mice were used, however, it was found that the fleas were not eaten. A study was therefore undertaken of the baby mouse as a host of *X. cheopis*, and in this paper the author gives an account of experiments which he made between 1937 and 1939.

The experimental technique is fully described and the resulting data are tabulated and graphed. At the beginning of each experiment, all fleas were unfed and under 24 hours old, and as the baby mice could not be fed they were changed every 24 hours.

Preliminary work showed that the fleas fed equally well on very young mice and on those 10 days old, and gave no support to the idea that a baby mouse might be a bad host because it was cold. It was also noted that when fed on

adult mice kept at 30°C fleas started to lay eggs after a delay of 1 day and though the daily production of eggs was unknown, the adult offspring per female per day was about seven.

Among fleas kept at a constant temperature and humidity (22° or 30°C. and 80 per cent. R.H.) for as long as 14 days, on baby mice of various ages up to 9 or 10 days old, there was almost no mortality but egg-laying started later (as much as 3 or 4 day) egg production was lower and adult progeny emerged later than was the case among fleas kept on an adult mouse under similar conditions. When fleas were allowed one initial feed on an adult mouse before being transferred to baby mice they continued for at least 18 days to lay more eggs than fleas which had fed only on baby mice.

Experiments at higher temperatures (32° and 34°C.) showed that parent fleas survived better on the baby than on the adult mouse and the adult mouse consistently killed more fleas. The number of progeny was lower and the individual fleas were smaller. At 34°C. there was no progeny either of adults or cocoons.

It is obvious that fleas fed on baby mice alone lack something, and this deficiency is greater the younger the mouse. The deficiency is apparently not in nutrition but more probably due to lack of a mammalian sex hormone. This point will be investigated.

H. S. LEROU

SILARIF M. The Water Relations of the Larva of *Xenopsylla cheopis* (Siphonaptera). *Parasitology* 1949 July & 39 Vol. 1/2, 148-55. [19 refs.]

The experiments described in this paper were designed in an attempt to discover how water is gained by the growing flea larva.

A quantitative study was made of the development of the larvae of *Xenopsylla cheopis* and statistical methods were applied to the experimental data to ascertain if certain aspects of biology varied when the larvae were reared under different conditions of moisture content both of food and of air. The criteria adopted were: the duration of the active larval life and of the combined larval and pupal life of both sexes; the mortality rate in different active larval instars and the period in which they died; the proportion of resting larvae that failed to pupate and the proportion of success in the rearing of adults and the disparity in their sex ratio.

At the commencement of each experiment the larvae were unfed and less than twenty-four hours old. They were put into small specimen tubes and kept at a constant temperature of 22°C. which is suitable for successful development and at a relative humidity of 60 per cent. which is low enough to magnify any differences under experimental conditions. The larval food was a mixture of blood and yeast which had been dried over concentrated sulphuric acid for three to five days or for fifteen days before being used. In some experiments the quantity of food was sufficient to cover the larvae (7 gm.) making a layer 3/16 in. deep. In these tubes larvae burrowed through the food to the bottom even though condition there was less favourable than on the surface. In other tubes the amount of food was not enough to cover the larvae even if they tried to burrow. Some experiments were run in which the food, both shallow and deep, was unchanged, and in others the food was changed either once or twice a day. Control experiments were made with deep food mixed with sand which had previously been brought into equilibrium by exposure to 60 per cent. relative humidity at 22°C. The course of each experiment is described in detail and the results are summarized in two columns (Tables). These show that in the control experiment 100 per cent. of the larvae completed their active larval life, 94.5 per cent. per individual cocoon and 95 per cent. of them emerged successfully. The proportion of the emerged adults

was significantly higher and their average combined larval and pupal life was significantly shorter than when they were reared in a large quantity of unchanged dry food, or in a small quantity of dry food whether changed or not. All the larvae died in the first instar, within seventeen days, when kept in a large quantity of dry food changed once or twice a day.

It is thus proved by controlling the quantity of dry food and its moisture content and the duration of its exposure to 60 per cent relative humidity at 22°C, that the chief source of the gain of water in the larva of *X. cheopis* is through its food.

INDIAN MED GAZ 1948, Mar, v' 83, No 3, 137-43 [30 refs] Plague
in Calcutta

This editorial article, by Lt-Col GREVAL, I M S (ret) is a suitable introduction to the following six papers dealing with the reappearance of plague in Calcutta which had remained free from indigenous cases of the disease since 1926.

The article will be of special interest to historians of plague in India. Several extracts are given from editorial articles in the *Gazette* during the early years of the original invasion of Calcutta and Bombay by the disease from 1895 onwards, these articles were by Dr W J SIMPSON who wrote with special authority because he was also Health Officer of Calcutta at the time. The yearly incidence of the disease in the two cities up to 1925 is also given.

There is a brief reference to the dramatic murder committed on the crowded platform of the chief railway terminus of Calcutta in 1933. This was by the injection, presumably by a hypodermic syringe, of a culture of plague bacilli into the victim who was the half-brother of the originator of the crime. The culture had been obtained from a bacteriological laboratory in Bombay by a medical man who posed as a research worker interested in testing the efficacy of a treatment of the disease and who was duly sentenced to death at the same time as the chief conspirator. For some reason the sentences were commuted to long terms of imprisonment, but the wicked half-brother after his release met a violent death during the civil disturbances of 1947.

The present outbreak is described as having lasted from March 6 to May 25, 1948 and as consisting of not more than 147 cases with 30 deaths, but a final note dated June 28 contains the information that no further cases have been reported since June 2nd 1948.

The antedating of the present issue of the *Gazette* by at least three months is likely to puzzle readers who find that events of April, May, and June are described in articles whose date of publication is stated as being March of the same year.

John W D Megaw

LAL, R B & SEAL, S C An Interim Note on certain Features of the Outbreak of Plague in Calcutta during March-May 1948 (corrected up to 10th May)
Indian Med Gaz 1948, Mar, v 83, No 3, 145-8

The authors describe an epidemiological study carried out between April 17 and May 10 1948, into the outbreak of plague in Calcutta.

Eleven cases, of which eight were fatal, had already occurred, but none had been recognized as plague till the commencement of the enquiry. From April 29 the number of cases rapidly increased so that during the next two weeks 105 had been reported, and by May 10 the total number of confirmed

case was 147. The case-fatality rate was 11.5 per cent, most of the life cases having been very mild. There were 84 other cases in which plague was suspected but excluded. Only three of the 33 wards and suburban areas of the city remained free from the disease, but the number of cases exceeded 10 in only five of these areas. Surprisingly, 134 of the cases occurred singly, three houses had two cases each, one house had three cases, and one had four.

The wide and rapid spread of infection is shown by the fact that between the 16th and 31st April first cases were reported from 77 of the 95 areas mentioned above.

Bacteriological examination of 891 rats trapped in 23 areas, was carried out between April 20 and May 10. Five strains of infection were isolated from 19 rats, of which seven were *Rattus rattus* and 12 were *R. norvegicus*. The heaviest rate of infection of rats was in the ward of the city in which the first case and the largest number of cases occurred, but one or more infected rats were trapped in 10 other areas. Infection doubtless existed in many other areas because in only nine of the 33 areas did the number of rats trapped exceed 20, so that the survey was admittedly inadequate.

The flea and *Y. cheopis* indexes, based on the examination of a limited number of rats, were as follows—

	Flea index	<i>Y. cheopis</i> index
April 19	2.5	2.5
4	11.5	4.0
29	8.7	2.9
May 10	Between 1.0 and 1.5	

The authors hesitate to express an opinion as to whether the outbreak heralds the beginning of a pandemic, but they find some indications that it may do so and they rightly insist that the situation ought to be handled on the assumption that the history of the previous visitation may repeat itself. They point out that Dr Simpson, Health Officer of Calcutta, diagnosed a case of plague in 1895 and that his warning of the danger was ignored.

John W. D. Meyer

ROY, D. N. A Note on Fleas and Rats with reference to Plague in Calcutta. *Indian Med Gaz.* 1948 Mar v 83 No. 3 149-50.

A concise description is given of the bionomics of rats and fleas in India, with special reference to the transmission of plague.

Mention is made of two previous surveys of the incidence of rat flea in Calcutta. The first was by STRICKLAND and the author in 1930 [this Bulletin 1930 v 27 731] when a low flea index was observed, the second was by RAO in 1941 (*ibid.* 1941 33, 622) when the index was 9.0 for *Rattus norvegicus* and 4.3 for *R. rattus*.

John W. D. Meyer

PANJA, G. & GUPTA, S. K. A Note on the Investigation of Suspected Plague Cases in the Campbell Hospital, Calcutta. *Indian Med Gaz.* 1948 Mar v 83, No. 3 148-9.

From April 16 onwards 77 cases were investigated by the authors at the Campbell Hospital. *Pasteurella pestis* was isolated from eight of the patients.

by gland puncture, but only one yielded a positive blood culture. All of the successful isolations were effected during the first few days of the investigation when only severe attacks were occurring.

Slide agglutination tests are said to have been very useful in identifying cultures of the organism and in the serological examination of the patients.

Sera of all the bacteriologically-positive patients who survived long enough contained agglutinins (titres 1-20 to 1-320) against recently isolated strains of *P. pestis* by the 7th to the 10th day of the illness. There was a positive reaction in only three of the bacteriologically-negative cases. Freshly prepared suspensions of 24-hour agar cultures were employed, and the reading of the slide test was made after one minute.

The large number of negative results is attributed to the mildness of the attacks and the use of sulphonamide drugs.

John W D Megaw

GUPTA, A K D A Short Note on Plague Cases treated in Campbell Hospital
Indian Med Gaz 1948, Mar, v 83, No 3, 150-51

Most of the patients attacked during the epidemic in Calcutta were treated at the Campbell Hospital where 129 [since corrected to 132] were dealt with up to May 25, 1948.

Between May 7 and May 25 severe cases predominated, and for the whole epidemic the bacteriologically positive cases numbered 21, all of these were positive with gland puncture and 13 were positive also with blood culture. Fourteen cases were classed as septicaemic, the rest as bubonic.

Three different lines of treatment were adopted (1) streptomycin injections, 24 of the severest cases were treated and there were seven deaths [since corrected to 4] (2) sulphadiazine by mouth, and (3) sulphamethazine, an initial dose intravenously, then four tablets every four hours. Among the 108 cases treated by sulphonamide drugs there were 11 deaths, but in the conditions prevailing it was not possible to express an opinion regarding the relative value of the different lines of treatment.

John W D Megaw

AHMAD, M U Recent Outbreak of Plague in Calcutta *Indian Med Gaz* 1948, Mar, v 83, No 3, 156

This is a brief note by the Health Officer of Calcutta who states that the control measures adopted were the isolation and treatment of patients in hospital, disinfection with DDT, epidemiological investigation and examination of rats under the supervision of the All-India Institute of Hygiene and Public Health, and mass inoculation.

PATEL, T B & REBELLO, J L An Assessment of the Value of Plague Vaccine (Haffkine Institute) as used in a Single Dose Mass Inoculation (A Field Enquiry) *Indian Med Gaz* 1948, Mar, v 83, No 3, 151-5

An attempt was made to assess the value of single doses of plague vaccine (2.0 cc) recently obtained from the Haffkine Institute, Bombay.

The enquiry was made after the subsidence of the epidemic, it dealt with 3,320 infected houses in 120 villages and seven municipalities. Despite the limitations of an enquiry held without previous planning the authors consider that certain broad conclusions can safely be drawn from their findings. The information collected has been analysed from several points of view, but the

Interaction of anti filtrate sera and filtrate—This was tested by mixing a 1 in 5 dilution of the serum with an equal part of the filtrate. After keeping the mixture for one hour in the waterbath at 37°C. and then two hours in the refrigerator the resulting precipitate was centrifuged off and the supernatant fluid titrated by the same method. The filtrates inactivated, to a considerable extent the neutralizing antibodies and the agglutinin against "O" suspensions the neutralization of "O" antibodies was however not complete and the titre of the serum against "OH" suspensions was only slightly lowered. Filtrates which had been rendered inactive by heating or by addition of formaldehyde lost their power of neutralizing the antibodies in the sera. The agglutinating titre against "O" suspensions however was lower in all sera, although the serum treated with boiled filtrate showed only a slight lowering of agglutinating power.

Both "O" agglutinating and protective antibodies on the other hand, were removed from the anti-filtrate sera by absorption with "O" suspensions. The significance of these differences is discussed—a possibility is that the "O" antigen in the solution in the filtrate may be more labile rather than qualitatively different from that of "O" suspensions but "the fact that suspensions of *V. cholerae* and autolysates of vibrios are free from F.F., however is very suggestive of some essential difference between F.F. and the somatic antigen of the vibrio." The difference cannot be defined on the available evidence.

Results similar to those with the Ogawa strain used were obtained with Inaba and Hikojima forms.

In a "discussion" the authors comment on the nature of the soluble substance obtained from cultures of *V. cholerae* that produces in the guinea-pig ileum, to a certain extent the pathological changes found in human cases of cholera. They consider that the production of F.F. may be connected with the virulence of strains, and that its action could explain most of the symptoms of cholera.

Reference is made to BURKET'S finding that F.F. is a mucin-splitting enzyme. Its possible status as a toxin is discussed. The discovery of F.F. will not alter the accepted methods of cholera vaccination at present—the antibodies produced by the somatic antigen in cholera vaccines protect guinea-pig ileum against the effect of cholera mucinase.

ANUJA, M. L. & GURKIPAL SINGH. Observations on Cholera Vaccine. *Indian J. Med. Res.* 1948 Jan. v 36 No 1 3-14

The response of human volunteers to inoculation with vaccines prepared from different forms of *V. cholerae* was studied by estimation of rise in bactericidal titre of their sera and the value of the sera for passive protection of guinea-pigs. Groups of six persons received a single dose of 1 cc. of a vaccine (800 million vibrios per cc.) consisting of a suspension 1 agar culture killed by 0.5 per cent. phenol. Three types were used, viz. pure Inaba form, pure Ogawa form and mixed Inaba and Ogawa in equal parts.

Bactericidal titre—Prior to inoculation, natural bacteriolytic for *V. cholerae* were found to be present in the sera at a maximum titre of 1 in 135 in seven, 1 in 45 in three and 1 in 15 or less in eight of the subjects. Ten days after inoculation of each group of 6 persons with one or other of the three types of vaccine bactericidal tests were carried out against both Inaba and Ogawa form suspensions, with different strains from those employed for the preparation of the vaccines. The dilutions used were from 1 in 15 to 1 in 300 (10). The sera of all subjects showed a rise in bactericidal titre the range being from 1 in 40 to 1 in 100 (10).

Bacteriolytic against both the homologous and heterologous forms were found to have been developed by inoculation with either of the pure-form

vaccines and with the mixed vaccine. In the majority of the subjects the bactericidal titre was higher against the homologous form than against the heterologous form, but in a number of the sera the titre for both strains was the same. With the strains used for the preparation of the vaccines, higher titres were obtained with pure Inaba vaccine than with the pure Ogawa or mixed vaccines. The response to inoculation was specific, no bactericidal action being shown against *Salmonella typhi*, *Bacterium coli* and three non-cholera vibrio strains.

A table in the text shows the level of agglutinin titre produced. In one case only the titre reached 1 in 125/250, but in the rest it varied from *nil* to 1 in 50/125.

The rate of development of bactericidal power was studied in three subjects inoculated with pure Inaba form vaccine. A gradual rise of titre was observed, which began on the 3rd day after inoculation, a considerable increase being shown by the 5th day and a maximum level being reached by the 8th day. By the 30th day, a considerable fall in titre occurred and the decline continued in the six months period of observation. The authors conclude that—"it can be assumed that up to the 3rd day there is practically no immunity, between the 3rd and 5th days there is partial immunity and after the 5th day there is considerable immunity", and also that—"for practical purposes the adoption of a six-day period for quarantine regulations is probably suitable although it appears that a high [higher?] degree of immunity would be obtained in 8 to 10 days."

The bactericidal response obtained on re-inoculation 6 months after the primary dose was found to be poor. In no case did it reach the level obtained by the primary stimulus and in some subjects no rise at all was shown.

Passive protection tests—These were carried out in guineapigs by intravenous injection of doses of sera of known bactericidal titre from inoculated subjects, in a range from 0.0001 cc. to 1 cc., followed four hours later by intraperitoneal injection of a mucinized suspension of a six-hour culture of *V. cholerae*. The results show the correlation between the passive protective value of the sera and their vibriocidal titre. A dose of 0.01 cc. of serum with a bactericidal titre of 1 in 100,000 protected guineapigs against the intraperitoneal test infection with a homologous vibrio strain, while no protection was obtained with 100 times that dose of the serum of a non-inoculated subject.

In similar tests with sera of subjects inoculated with pure Inaba or Ogawa form or mixed vaccine, and challenged by both, the sera of those inoculated with the mixed-type vaccine were found to have passive protective substances in a greater concentration than sera of those immunized with a pure Inaba or pure Ogawa vaccine.

Active immunization of guineapigs—No significant difference was found in the results of immunization of guineapigs with either the pure type or mixed vaccines, when challenging doses of both the Inaba and the Ogawa form were used. "An Inaba strain vaccine affords just as good protection against Inaba infection as against Ogawa infection and vice versa."

[One level only of challenging dose appears to have been employed, and no indication is given of the number of lethal doses contained.]

The authors do not consider that the active immunization of mice or guineapigs is suitable as the sole criterion for determining the relative merits of strains for use in the preparation of cholera vaccine, and prefer the passive protection test as being more sensitive. They find the development of agglutinins after cholera vaccination to be at too low a level for assessing the degree of immunity produced. "The infection-resisting capacity of protective substances present in the sera of vaccinated subjects is higher for homologous than for heterologous sub-type infection."

SEAL, S. C. On the Control and Prevention of Endemic Cholera in the Rural Areas of Bengal. *J India Med Ass* 1948, July v 17 No. 10 319-71

Suggestions are made for (a) short term or temporary measures and for (b) long term or permanent measures for the control and prevention of cholera in rural Bengal.

The short term measures recommended are (1) early notification by the village authority (2) visit by a health officer with suitable supplies for disinfection and treatment (3) treatment of the cholera case with sulphaguanidine and oral administration of *slab* water or sodium-bicarbonate-glucose solution (intravenous saline only in advanced cases) (4) prophylactic administration of acid mixture (3 parts acid sulphuric aromatic and 1 part *spt* chloroform, in water) to all contacts, and sulphaguanidine to contacts showing suspicious symptoms (5) isolation and hospitalization of cases in temporary *shed* or mobile camps (6) anti-cholera inoculation. (The author has considered it advisable to a *old* inoculation of the members of an affected family for at least three days as there may be a risk that the measure would be discredited if members inoculated during the incubation period develop cholera.)

Long term measures.—The author considers that "Investigation into the local circumstances and factors which operate in causing repeated outbreaks is a pre-requisite for planning effective preventive measures." For the purpose it is suggested that a "special Epidemic Control Unit" should be formed to take care of the infectious diseases of a sub-division with an average population of 800,000 at an annual cost of about $\frac{1}{2}$ anna *per r* *pat*. While carrying out control work, the Unit would keep continuous records of communicable disease in its area which might be used for forecasting epidemics so that early measures could be adopted to abort them.

The provision of a Segregation Cottage in each village is advocated so that early cases may be isolated. The author does not consider general yearly reinoculation to be feasible but for the prevention of importation of infection believes that cholera could be greatly reduced by insistence on inoculation 7 days before departure to attend a *wida* or a religious congregation and on yearly reinoculation for those regularly visiting trading centres or industrial areas. For reinoculation the author prefers the intradermal administration of 0.1 cc. of the vaccine.

The importance of *mela*s and pilgrimages in the dissemination of infectious disease is recognized by the recommendation for the provision of permanent sanitary arrangements at major perennial centres and for special measures at smaller *mela*s and festivals of short duration.

The necessity for health teaching in school and community life is stressed. [The measures of more permanent nature which are essential for the reduction of the risk of cholera in the endemic areas are not dealt with in this paper, namely provision of protected water supplies and improvement in environmental sanitation.]

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

HANSEN, E. L. & ANDERSON, H. H. An Essentially Synthetic Liquid Medium for *Entamoeba histolytica*. *Parasitology* 1948, July v 39 No. 1/2 69-72. (13 refs.)

The nutritional requirements of *Entamoeba histolytica* in culture with "organism 1" were studied, and a liquid medium was devised to maintain the amoebae in an actively reproducing form. Subcultures were performed every

four days by which time the amoebae numbered 400,000 per culture tube, the transfer consisting of 0.25-0.5 cc of the sediment. The medium was prepared from stock solutions kept at varying concentrations and diluted to the necessary strength with distilled water, sterilization was effected by autoclaving at 120°C for 7 minutes. The pH range was from 7.48 on the day of transfer to 7.1 in four-day-old cultures. The medium contained the following constituents—buffered saline, 5 trace minerals, 12 amino-acids, 10 vitamins of the B complex, nucleic acid, cholesterol and, finally, rice powder, the only non-synthetic ingredient though the presence of the organism *I* was also essential for proper growth. The critical requirements of the ingredients are being further studied.

DERRICK, E. H. A Fatal Case of Generalized Amoebiasis due to a Protozoon closely resembling, if not identical with, *Iodamoeba bütschlii*. With a Comment by C. M. WENYON. *Trans Roy Soc Trop Med & Hyg* 1948, Sept., v. 42, No 2, 191-8, 21 figs on 4 pls

This unique case of amoebiasis differed from other fatal cases that occurred in Japanese prisoners of war in the wide and bizarre distribution of lesions. The stomach, small intestine and colon were ulcerated, and metastatic foci were present in the brain, both lungs, gastric and mesenteric lymph glands, but not in the liver. In most of the lesions the amoebae are exceedingly numerous.

The organism is definitely not *Entamoeba histolytica*, but closely resembles *Iodamoeba bütschlii*. The patient, a Japanese soldier, aged 22, was captured near Buna, New Guinea. He was treated for malaria and dysentery, but failed to respond and died on the sixth hospital day. At post-mortem, the surface of the brain showed a depressed area in the lateral aspect of the right parieto-occipital region. The stomach showed numerous shallow ulcers, they were rounded, irregular or confluent. In the small intestine at the midpoint there was an ulcer with yellow edges and congested floor. Seven rounded ulcers were present in the large intestine, resembling those in the small. The presence of amoebae, often in enormous numbers, is the most significant feature in the histology. They show the same morphology everywhere. In size they vary considerably—the extremes being 3 μ and 12 \times 9 μ —averaging 6-8 μ , about that of the neutrophil leucocytes.

The cytoplasm, granular and foamy, occasionally includes small vacuoles and ingested red blood corpuscles, especially in the brain lesion. The nucleus usually measures 2 to 2.5 μ in diameter and consists of a large, central karyosome, surrounded by a clear zone which in turn is encircled by a delicate nuclear membrane. Sometimes the karyosome is indented, and this may represent a stage in division. Occasionally the amoebae contain two nuclei, which is evidence of their rapid multiplication. No forms resembling cysts were recognized. The large central, spherical karyosome and delicate nuclear membrane resemble those of *Iodamoeba*. The size of the trophozoites is also consistent with that reported for *I. bütschlii* in faecal smears. [No adequate examination of the faeces appears to have been made.]

In its behaviour in the tissues, this amoeba resembles *E. histolytica* but the distribution of the lesions is unusually extensive, even for *E. histolytica*, and histolytic action is well demonstrated in the brain sections where red cells are being ingested. As with *E. histolytica*, so in the intestinal ulcers, amoebae are found most frequently beyond the area of cellular reaction. Dr C. M. Wenyon also examined the material in consultation with Dr C. A. Hoare and agreed that the similarity with *I. bütschlii* amounts almost to complete identity. It would not be justifiable to consider the amoeba as a new species. It appears to be an instance of unusual invasion of the various organs by an amoeba from the intestine.

SEAL, S. C. On the Control and Prevention of Endemic Cholera in the Rural Areas of Bengal. *J Indian Med Ass* 1943 July 17 No. 10 319-1

Suggestions are made for (a) short term or temporary measures and for (b) long term or permanent measures for the control and prevention of cholera in rural Bengal.

The short term measures recommended are (1) early notification by the village authority (2) visit by a health officer with suitable supplies for disinfection and treatment (3) treatment of the cholera case with sulphaguanidine and oral administration of 4 lb water or sodium-bicarbonate-glucose solution (intravenous saline only in advanced cases) (4) prophylactic administration of acid mixture (3 parts acid sulphuric aromat and 1 part spt. chloroform, in water) to all contacts and sulphaguanidine to contacts showing suspicious symptoms (5) isolation and hospitalization of cases in temporary sheds or mobile camps, (6) anti-cholera inoculation. (The author has considered it advisable to avoid inoculation of the members of an affected family for at least three days as there may be a risk that the measure would be discredited if members inoculated during the incubation period develop cholera.)

Long term measures.—The author considers that "investigation into the local circumstances and factors which operate in causing repeated outbreaks is a pre-requisite for planning effective preventive measures." For the purpose it is suggested that a "special Epidemic Control Unit" should be formed to take care of the infectious diseases of a sub-division with an average population of 800 000 at an annual cost of about 1 anna per capita. While carrying out control work, the Unit would keep continuous records of communicable disease in its area, which might be used for forecasting epidemics so that early measures could be adopted to abort them.

The provision of a "Segregation Cottage" in each village is advocated so that early cases may be isolated. The author does not consider general yearly reinoculation to be feasible but for the prevention of importation of infection believes that cholera could be greatly reduced by insistence on inoculation 7 days before departure to attend a *mela* or a religious congregation and on yearly reinoculation for those regularly visiting trading centres or industrial areas. For reinoculation the author prefers the intradermal administration of 0.1 cc. of the vaccine.

The importance of *melas* and pilgrimages in the dissemination of infectious disease is recognized by the recommendation for the provision of permanent sanitary arrangements at major perennial centres and for special measures at smaller *melas* and festivals of short duration.

The necessity for health teaching in school and community life is stressed. AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

HANSEN E. L. & ANDERSON H. H. An Essentially Synthetic Liquid Medium for *Entamoeba histolytica*. *Parasitology* 1948, July 33 No. 1/2 69-72. [13 refs.]

The nutritional requirements of *Entamoeba histolytica* in culture with "organism 1" were studied, and a liquid medium was devised to maintain the amoebae in an actively reproducing form. Subcultures were performed every

medium recommended by CHORINE [see this *Bulletin*, 1943, v 40, 917] with fresh rabbit serum, gave negative results in all subcultures. Experiments on the culture of the spirochaetes in incubating eggs gave 12 negative results and 7 positive, the number of passages in these ranging from 1 to 19. It was found necessary to use only two drops of heavily infected defibrinated blood (or slightly citrated), and the blood had to be inoculated as soon as possible. For passages from egg to egg, the blood of the embryos was mixed with the allantoic fluid and slightly citrated. When successful, the spirochaetes appear in the blood of the embryo 3 or 4 days after inoculation, and persist until the embryo is ready to hatch. The passages are very difficult and irregular, and after the 14th passage the spirochaetes undergo morphological changes suggestive of degeneration.

BALTAZARD, M., BAHMANYAR, M. & MOFIDI, C. Sur les infections à spirochetes transmises par les Ornithodores en Iran [On Spirochaetal Infections transmitted by *Ornithodoros* in Iran.] *Bull Soc Path Exot* 1948, v. 41, Nos 3/4, 141-6

The authors have examined the two species of rodents commonly associated with man in Iran, namely the common mouse *Mus musculus*, and the small hamster *Cricetulus migratorius*, to see whether they act as reservoirs of *Spirochaeta persica*, transmitted by *Ornithodoros tholozani*.

Numbers of these rodents were caught in houses in a small village, Hessarek, during January to March 1946, 65 mice and 69 hamsters were killed in lots of 3 or 4, and an emulsion of the brains of each lot was inoculated into a guinea pig rat and mouse, respectively. On only one occasion was a spirochaete isolated from wild mice, and this was found to be *S. persica*. Subsequently a total of 127 mice, 380 hamsters, 4 bandicoots, 25 *Rattus norvegicus*, 5 *R. alexandrinus*, 83 *R. frugivorus*, 4 porcupines and 2 foxes were examined, with negative results so far as this spirochaete was concerned. On the other hand, an organism described by RAFYI [see this *Bulletin*, 1947, v 44, 92] as *Spirochaeta microti*, was often found in both mice and hamsters. Large numbers of *Ornithodoros erraticus* were collected from the burrows of animals in various parts of Iran and by feeding these ticks on white rats, 15 strains of *S. microti* were obtained. These varied considerably in their pathogenic properties, some strains producing either inapparent infections or blood infections of only 24 to 48 hours duration, and others an infection with spirochaetes in the blood for 28 days.

Two human subjects inoculated with blood containing numerous spirochaetes, showed a slight febrile reaction with the presence of very rare spirochaetes in the circulation. Another subject was bitten by naturally infected *Ornithodoros* from a burrow, and showed a febrile reaction, but without any spirochaetes being found in the blood, another person bitten by ticks infected in the laboratory showed a febrile reaction associated with the presence of rare spirochaetes.

Finally the author gives a list of spirochaetes from the Old World rodents which seem to be either identical or closely related, and all transmitted by species of *Ornithodoros*, as follows —

Spirochaeta crociduræ Léger, 1917, in Dakar, transmitted by *O. erraticus*

S. naganophila Savini, 1923, in white mice

S. normandi C. Nicolle, Anderson and Colas-Belcour, 1927, in South Tunisia, transmitted by *O. normandi*.

The spirochaete isolated from the brain of a rodent at Katanga by Adant, 1932. The spirochaete found in *O. erraticus* in South Morocco by Baltazard and subsequently in rodents by G. Blanc and provisionally named *Spirochaeta merionesi*.

On the analogy with *E. histolytica* which often exists in the intestine without further invasion, it is reasonable to assume that conditions arose which enabled this common coprozoid species to invade the tissues.

The phagocytosis of red blood cells by *E. histolytica* has not been previously recorded.

The paper is illustrated by 3 photographs and 18 excellent photomicrographs.
Manson Bahr

CRITCHLEY C. I. Liver Abscess: Sporadic Amoebiasis. [Memoranda.] *Brit Med J* 1948 Oct. 9 681 2.

This letter relates to a man of 34 who had never been out of Britain nor had had any tropical associations, but who developed a liver abscess without previous illness.

He presented with a history of five-day epigastric pain worse on deep inspiration and associated with vomiting. No mass was felt and the liver was not palpable. There was a leucocytosis of 27,000 per cmm. (81 per cent. neutrophils) and the diaphragm on X-ray examination was shown to be raised about 1 inch. After 5 days of continued symptoms the abdomen was opened and a large very soft liver was found reaching to the right iliac fossa. Five pints of "anchovy-sauce" pus were aspirated on exploration of the right lobe of the liver; a further loculus yielded one pint of yellow pus. Penicillin (100,000 units) was instilled in the cavity which was drained.

The pus was sterile and no amoebae nor cysts were found in it nor in the stools on repeated examination. No radiographic abnormality was found in the bowel. Sigmoidoscopy showed "the smooth pale glossy and rather rigid mucous membrane associated with chronic amoebiasis." A full anti-amoebic course was therefore given with immediate and dramatic response.

[The nature of the anti-amoebic treatment or of the dramatic response is not described. The latter is complicated by the fact of penicillin having been given in a case where examination of the pus was negative. However significant the findings as the present data undoubtedly are, an unqualified diagnosis of sporadic amoebiasis in the absence of amoebae, specific changes in the bowel or of known exposure and in the presence of a marked neutrophile leucocytosis, is perhaps a bold one.]

NIGO F. L. Estudio clínico y parasitológico de un caso de colitis leve por asociación de *Balantidium coli* y *Endamoeba dysenteriae*. [A Case of Ulcerative Colitis associated with the presence of *Balantidium coli* and *Endamoeba histolytica*.] *Revista Med. 4 germa.* 1948 Aug 13, v 35 No. 33 1901-4 15 figs.

RELAPSING FEVER AND OTHER SPIROCHAETOSIS

BALOGH L. Le spirochète de la récurrent de la dernière épidémie de spirochétose Nord Africaine. [The Spirochaeta in the Last Epidemic of North African Relapsing Fever.] *Bull. Soc. Path. Exot.* 1948, v 41 Nos. 3 & 4 146-9.

The author has studied the properties of a strain of the louse-transmitted spirochaete isolated from cases of the disease during the great epidemic in North Africa (see this Bulletin 1948 v 43 44). Inoculation into mice produced very slight infections which only lasted for a few hours and it was never possible to continue passages in mice. Attempts at cultivation with the

Spirochaeta microti is of the same type and all these strains are transmissible both by *Ornithodoros erraticus*, and probably allied species, and also by lice. As the infection is widely distributed in rodents they constitute a source of danger, especially as they can be transmitted by *Pediculus*.

This group of spirochaetes, probably identical with *S. crociduræ*, is very distinct from those belonging to the *duttoni* group which have different biological properties and are transmitted by other species of *Ornithodoros*. *E. Hindle*

ZAHARIA, N. I. Viteza de sedimentare a hematului in cursul febrei recurente [The Erythrocyte Sedimentation Rate in Relapsing Fever.] *Rev Ştiinţelor Med* Bucharest 1948, May-June, v 37, Nos 5/6, 209-17, 2 figs. French summary

The author in 1945-46 working in the Stamate Hospital, Fălticeni, Rumania, studied the ESR daily in 58 cases of relapsing fever. Several variations were recognized, but in general the rate was markedly increased both during an established attack and when there were few or no symptoms. Between the attacks, levels became more or less normal, and they returned completely to normal about 5 to 15 days after the end of the disease.

These findings in relapsing fever appear to be the reverse of those observed by the author previously in cases of epidemic typhus (*Rev Ştiinţelor Med*, 1946, v 35, 317) and he suggests that this difference might be of value in differential diagnosis in some cases.

The findings are illustrated graphically in two figures.

YAWS

SCHIRPENHUYSEN, A. A. Bismuth en behandeling van framboesia tropica [Bismuth in the Treatment of Yaws] *Nederl Tijdschr v Geneesk* 1948, Sept 4, v 92 (III), No 36, 2741-9 [17 refs] English summary (7 lines) [20 refs]

A total of 2 067 sufferers from yaws were treated with bismuth, with mapharsen or with bismuth combined with arsenical preparations. It became apparent from the duration and from the results of treatment that the three methods gave practically the same results. Possibly those patients treated with mapharsen were more satisfactory. The favourable results of the work of a mobile anti-yaws team are commented upon. The author was medical officer to the 13th mobile team of the Netherlands Red Cross, working on the east coast of Sumatra.

LEPROSY

TEICHMANN, G. O. What of the Children? *Leprosy in India* 1948, Apr, v 20, No 2, 103-8

This obscure title refers to a valuable report on the ultimate results in children treated at the 6 Children's Homes in the Purulia Leper Home and Hospital during the past 20 years including those in the Home before 1927, since when accurate records have been kept, and those admitted during three 5-year periods up to 1942. Only 2 of 63 healthy children, who had been exposed to infection before admission, developed leprosy previously to 1927 against a possible infection rate in their infected homes of 25 to 30.

S. latyscheki found in the rodents of Uzbekistan by Pavlovsky and his fellow workers in 1945 transmitted by *O. tartakowskyi* [See this Bulletin, 1946, v 43 743]

Finally *S. microi* found in Iran by Rafiyi in 1946 described in the present communication
E. H. HALL

DELPHY L. P. RAFFI A. & MAGHAMI G. D. Transmission de *Spirochaeta microi* Rafiyi 1946 par *Ornithodoros canestrini* (Birula 1894) et *Ornithodoros lahorensis* Neumann 1908. [The Transmission of *Spirochaeta microi* Rafiyi 1946 by *Ornithodoros canestrini* (Birula 1894) and *Ornithodoros lahorensis* (Neumann 1908)] Bull. Soc. Path. Exot. 1948, v 41 Nos 34 138-9

The authors have succeeded in transmitting *Spirochaeta microi* from infected rats or mice to normal rats by the bites of *Ornithodoros canestrini* and *Ornithodoros lahorensis*. The ticks were fed on the infected rodents and then after intervals ranging up to 300 days, fed on normal rats or in one case, the content of the tick were ground up and inoculated into rats.

It is curious that these ticks can serve as the host of this spirochaete of wild rodents as hitherto all attempts to transmit *S. persica* by these two species had given uniformly negative results.
E. H. HALL

BALTAZARD M. MOFIDI, G. & BAKMANYAR, M. Essai de reclassement de certains spirochètes récurrents. [An Attempt to reclassify certain Relapsing Fever Spirochaetes.] Bull. Soc. Path. Exot. 1948, v 41 Nos. 58 309-403.

The authors summarize information on the spirochaete found in rodents and also in *Ornithodoros erraticus* collected in burrows in both north and north Iraq. This organism, known as *Spirochaeta microi* is transmissible both by ticks and also the louse *Podoculus humanus*.

The study is based on the examination of 17 strains. New-born rodents can be infected either by the inoculation of blood containing spirochaetes or the bites of infected *Ornithodoros*. The incubation period is always less than five days and invariably fatal on the 2nd to 4th day of infection with very large numbers of spirochaetes in the blood. White mice grey mice hamsters bandicoots, white rats and rabbits give similar results but new-born guinea pigs which are born at a later stage of development are resistant and only show a feeble infection which is never fatal.

Adult mice after inoculation show an incubation period of 8 days followed by 10 to 12 days during which the blood may contain up to 100 spirochaetes per field. The type of infection in these animals is very constant. Other rodents show very great differences in their susceptibility and adult guinea pigs seem to be completely resistant.

The pathogenicity of 3 strains has been tested in 9 human subjects. Some were inoculated with infected blood and others infected by the bites of *Ornithodoros erraticus*. There was an incubation period of 4 to 10 days, followed by 3 to 5 febrile attacks not exceeding 3 days each and with a total duration of 30 to 51 days. Spirochaetes were found in the blood usually only after several examinations, and were never numerous. No meningeal or nervous symptoms were ever observed.

The authors then studied a strain of *S. marsei* from South Morocco, and found that it was much more virulent to white rats hamsters, etc. often producing a fatal infection.

Finally the original strain of *S. erousaei* isolated at Dakar more than 20 years previously was obtained and in its properties found to resemble closely *S. marsei*.

Spirochaeta microti is of the same type and all these strains are transmissible both by *Ornithodoros erraticus*, and probably allied species, and also by lice. As the infection is widely distributed in rodents they constitute a source of danger, especially as they can be transmitted by *Pediculus*.

This group of spirochaetes, probably identical with *S. crocidurae*, is very distinct from those belonging to the *duttoni* group which have different biological properties and are transmitted by other species of *Ornithodoros*. E Hindle

ZAHARIA, N I Viteza de sedimentare a hematului in cursul febrei recurente [The Erythrocyte Sedimentation Rate in Relapsing Fever] *Rev Științelor Med* Bucharest 1948, May-June, v 37, Nos 5/6, 209-17, 2 figs French summary

The author in 1945-46 working in the Stamate Hospital, Fălticeni, Rumania, studied the ESR daily in 58 cases of relapsing fever. Several variations were recognized, but in general the rate was markedly increased both during an established attack and when there were few or no symptoms. Between the attacks, levels became more or less normal, and they returned completely to normal about 5 to 15 days after the end of the disease.

These findings in relapsing fever appear to be the reverse of those observed by the author previously in cases of epidemic typhus (*Rev Științelor Med*, 1946, v 35, 317) and he suggests that this difference might be of value in differential diagnosis in some cases.

The findings are illustrated graphically in two figures

YAWS

SCHERPENHUYSEN, A A Bismuth en behandeling van framboesia tropica [Bismuth in the Treatment of Yaws] *Nederl Tijdschr v Geneesk* 1948, Sept 4, v 92 (III), No 36, 2741-9 [17 refs] English summary (7 lines) [20 refs]

A total of 2,067 sufferers from yaws were treated with bismuth, with mapharsen or with bismuth combined with arsenical preparations. It became apparent from the duration and from the results of treatment that the three methods gave practically the same results. Possibly those patients treated with mapharsen were more satisfactory. The favourable results of the work of a mobile anti-yaws team are commented upon. The author was medical officer to the 13th mobile team of the Netherlands Red Cross, working on the east coast of Sumatra.

P Manson-Bahr

LEPROSY

TEICHMANN, G O What of the Children? *Leprosy in India* 1948, Apr, v 20, No 2, 103-8

This obscure title refers to a valuable report on the ultimate results in children treated at the 6 Children's Homes in the Purulia Leper Home and Hospital during the past 20 years, including those in the Home before 1927, since when accurate records have been kept, and those admitted during three 5 year periods up to 1942. Only 2 of 63 healthy children, who had been exposed to infection before admission, developed leprosy previously to 1927 against a possible infection rate in their infected homes of 25 to 30.

One hundred and fifty-one children were in the Homes in 1927. Of 63 in the "Healthy Homes" where the children have been separated from leprosy relations 56 (89 per cent.) are now well. Of 54 with neural leprosy 23 are well, but of 34 lepromatous cases none are well. 18 are dead and only "improved" debility and tuberculosis were the common causes of death. Between 1927 and 1942, 120 children were admitted to "Healthy Homes" 36 are still well and remain in the Homes. 56 are at work or married many with healthy children. 23 developed signs of leprosy and were returned to the Colony but only six now have active disease, 11 are dead and 11 untraced.

Again 120 children were admitted after 1927 to "Observation Homes" for neural cases and those in whom bacilli cannot be found, and 73 are still well. 13 have active disease 9 are much better. In 7 the disease is arrested with deformity 8 are dead and 10 untraced. Similarly of 132 children admitted to "Infectious Homes" in 1928 to 1942, 6 remain healthy 26 improved and left, 73 still have active disease 4 have arrested disease with deformity 20 are dead and 4 untraced. Thus children who were separated from their infected parents either remained free or developed only a mild form of leprosy the great majority of them becoming symptom-free without deformity on treatment these children did not show the severe form they often show if left with their infected parents or relations. The use of this plan on a large scale should therefore result in far fewer leprosy cases later.

JUÁN PUIGRÓS P. Una cepa española del *Myc. leprae* (Harven) Lehmann et Neumann. [A Spanish strain of *Mycobacterium leprae*] *Rev. Fisiol. Valencia*. 1948 Jan. v. 2, No. 1, 33-45. 6 figs. on 3 pls. [109 refs.] English summary

After a brief sketch of the numerous reports of bacteria cultivated from leprosy patients the author describes an organism isolated from a leproma carefully removed triturated and planted on various media, and part homogenized for studying the morphology of the many bacteria present. Morphologically those isolated were typically like *Myc. leprae* and stained in the same way. Growth was slow after 3 years the colonies were only 8-10 mm. in diameter on Löwenstein's red and Löwenstein's green media, on Dorset-Petroff, Petragiani without asparagine, or de Saenton and vitamin B and C. There was no growth on the ordinary media. The organism will grow at room temperature but the optimum is 36-38°C. It is pathogenic to the white rat the mouse the guinea pig and the rabbit.

The author maintains that it is a strain of *Myc. leprae* on the grounds of its morphology and staining reactions, of its not belonging to the acid-fast saprophytic group of its pathogenicity for rats and mice. It differs from John's bacillus. It was obtained from a leproma extirpated aseptically. In conclusion, he compares it with and indicates the differences from the organisms of Duval and Clegg, Barry Hedrowsky, Llera, Vandremmer, Reentjerna and others.

ALVAREZ LOWEL, L., RODRIGUEZ PEREZ, A. P. & PUIGRÓS, J. R. La participación de los centros nerviosos en el sustrato histopatológico de la lepra. [The Histopathology of the Nervous Centres in Leprosy] *Rev. Fisiol. Valencia*. 1948 July v. 2, No. 2, 101-14. 23 figs. on 8 pls.

The authors have studied the morbid histology of the nervous system, central and peripheral, in three cases of leprosy. Fragments were fixed in 10 per cent formalin in 15 per cent neutral formalin, in Cajal formalin bromide and in rectified

spirit Some sections were made of frozen tissues and some by the paraffin-embedding method Several silver impregnation methods were used, as well as haematoxylin and eosin, and Sudan III The different parts, the peripheral nerves, neuroglia, grey and white matter are described in minute detail The posterior tracts, particularly that of Goll, are picked out and, to a less extent, the lateral tract Higher up the nerve cells are degenerated and there is marginal and perivascular gliosis In general it is said that the response is that characteristic of toxic action leading to central degeneration, secondary to initial gliosis In the optic nerve and chiasma there is acute oedema of the dendroglia "The histological picture is in part due to peripheral lesions arising in the ganglia and nerves, and in part to toxic processes similar to those met with in chronic, non-specific affections" The conditions described in the text are well shown in a series of 23 photomicrographs H Harold Scott

DE DULANTO, F La biopsia por aspiración de la médula ósea en la lepra Técnica y resultados [The Bone Marrow in Leprosy] Rev "Fontilles" Valencia 1948, Jan, v 2, No 1, 4-16, 8 figs (7 on 4 pls) [36 refs]

LOWE and DHARMENDRA found, in 16 out of 32 nodular leprotics, bacilli in the bone marrow, but in only one out of 18 with the nervous type of the disease The author has examined the marrow obtained by sternal puncture in 13 patients with "leprotic leprosy" [*i.e.* with lepromata] and 8 with the leprous reaction By the usual method he withdraws 2-3 cc of marrow In 6 of the 13 with lepromata he found *Myco leprae*, in two of them typical Virchow cells charged with the bacilli In all these, the skin, the nasal mucosa and the lymph glands were also positive, as they were even in those whose marrow proved negative The myelogram showed, in addition to the Virchow cells, a meta-myelocytosis, eosinophiles normal or slightly increased and an erythroblastic reaction The peripheral blood of the positive cases showed a neutrophilia, a slightly increased eosinophilia (but not constantly), monocytes on the high side, in the reactions up to 15-20 per cent The marrow changes are ascribed to simple inflammatory or specific granulomatous lesions with inadequacy of haemopoiesis and consequent anaemia and leucopenia in the peripheral blood slides

Since the sulphone derivatives—promin, diasone, promizole, sulphetrone—provoke haemolytic anaemia and leucopenia, even agranulocytosis, it is thought that periodic examination of the marrow may serve to indicate danger arising from the use of these drugs H Harold Scott

SCHUJMAN S. Comparative Study of Chaulmoogra in High Doses and Promin in the Treatment of Leprosy. *Internat. J. Leprosy*, 1948, Apr-June v. 16 No. 2 145-6

The author in Rosario, Argentina, injected both intramuscularly and intradermally monthly doses of 120 to 150 cc., according to tolerance of ethyl ester chaulmoograte with 4 per cent creosote or 0.5 per cent iodine. Promin was given intravenously in doses of 5 gm. daily except on Sundays, up to a total of 500 gm. in a series, with fifteen days rest after each series. Although no patient gave up treatment, chaulmoogra caused more discomfort than promin. Treatment for eighteen months showed both drugs to be efficient with similar favourable results within the same period of time as regards both dermal and mucous membrane lesions and with the same fragmentation and diminution of lepra bacilli and healing of erosions and ulcerations. Longer observations are necessary to establish whether one of the two is more effective.

L. Rogers

COCHRANE R. G. A Comparison of Sulphones and Hydnocarpus Therapy of Leprosy. *Internat. J. Leprosy*, 1948 Apr-June v. 16 No. 2, 139-44

The author only considers the lepromatous class of cases in which sulphones have been favourably reported on. He concurs in the opinion of SCHUJMAN (this Bulletin 1948, v. 45 441) that the success of hydnocarpus treatment is largely dependant on dosage up to 400 cc. in a year and on the use of the intradermal method. Six years work showed 17.5 per cent. negative and 40.2 per cent. improved by equal dosage subcutaneously and intradermally against 12.3 per cent. and 34.2 per cent. respectively with 15 cc. of the oil injected per week, which is the optimum dose. Moreover in 167 early lepromatous cases 84 (50.3 per cent.) became negative under adequate dosage of hydnocarpus oil after an average of 84 weeks treatment.

On the other hand, two years trial of sulphones confirmed the work of PAGET and others although no case has yet become negative bacteriologically so the time required to effect this is still too long. Promin was the least satisfactory preparation and too toxic for Indian patients. Sulphetone appears to be the drug of choice for dissonant precipitates reactions in 23 per cent. of cases. The author prefers to commence with 4 tablets a day and increase by two every second day up to 12 daily and does not allow any rest period unless the red corpuscles fall below 3 million and the haemoglobin below 45 per cent. The bowels must be kept freely open as constipation may be dangerous.

The disadvantages of sulphone treatment are the necessity for close daily supervision and the present prohibitive cost for large numbers of Indian patients. The author therefore gave sulphetone in an emulsion with 25 per cent. arachis oil and 0.5 per cent. beeswax to obtain blood level of 1 to 3 mgm. per cent. and skin concentrations of 5 to 17 mgm. per gramme of skin tissue on

injection, by which means relatively small doses are required. Thus, in two similar cases much greater improvement clinically and bacteriologically was obtained by the injection of 70 gm of a 25 per cent suspension of diamino-diphenyl sulphone in eleven months than by giving 2,471.5 gm of sulphethrone orally for 16 months. A method of examining sixteen smears from each patient to obtain a bacteriological index is advised for the control of results.

The author therefore advises sulphones only in advanced lepromatous cases, especially those with nasal and laryngeal symptoms, and in cases not improving on adequate hydnocarpus treatment or who have relapsed. Intensive intra-dermal use of hydnocarpace is insisted on, as it accounts for the better results in lepromatous cases under hydnocarpace than under sulphones in Indian patients.

SHARP, E A & PAYNE, E H The Present Status of the Sulfones in Therapy
Internat J Leprosy 1948, Apr-June, v 16, No 2, 157-72 [161 refs]

This paper, which should be read by those interested deals mainly with history of sulphone preparations. Promin has proved not to be dangerously toxic. Promizole is useful in leprosy, but is difficult to make and is expensive. Promacatin is of use in pneumonia and leprosy and diasone and sulphethrone in the latter disease. Benadryl is a useful adjunct in treatment of the lepra reaction.

L Rogers

DE SOUZA LIMA, L & others Present Status of Sulfone Therapy at the Padre Bento Sanatorium
Internat J Leprosy 1948, Apr-June, v 16, No 2, 127-37

This is a report on the sulphone treatment in 1,287 leprosy patients during four and a half years in São Paulo, Brazil. The results confirm other experience and establish its value. The disease ceases to progress after from three to six months regardless of the degree of advancement of the case. For example, none of 847 lepromatous cases treated for 12 to 36 months have grown worse, but 4.2 per cent did not improve. During the first six months, temporary aggravation of the symptoms may occur in 12 to 15 per cent of the patients, but later no relapses have occurred. The degree of improvement varies from slight to total disappearance of the lesions. The beneficial results affect mucous membranes of the nose, mouth, pharynx and larynx, and tracheotomized patients have been able to dispense with their tubes. The progress of eye lesions to total blindness has also been almost entirely prevented under intensive treatment, and extensive corneal infiltrations may largely clear up and become free from lepra bacilli.

A table based on 584 advanced lepromatous cases shows lesions cleared in 8 per cent, much improved 24 per cent, improved 64 per cent and unchanged 4 per cent. In about 7 per cent improvement became stabilized and remained stationary after 18 to 20 months' treatment. In 50 per cent, eruption of erythema nodosum, or less frequently of erythema multiforme, occurred, this is regarded as a favourable sign. Better results were seen in 158 moderately advanced lepromatous cases with 53 per cent cleared up, 34 per cent much improved, 9 per cent improved and 4 per cent unchanged. Another table deals with 99 incipient cases, with 67 per cent cleared up, 14 per cent much improved, 19 per cent improved and none unchanged or worse, the advantage of early treatment is thus apparent.

On the other hand, in lesions of the peripheral nervous system the results have been nil or insignificant, so it is important to start treatment early, before such lesions have occurred.

In tuberculoid cases the tendency to spontaneous recovery makes it difficult to evaluate the effects of sulphone treatment. Some tuberculoid cases pass into the lepromatous form, or invade nerves with resulting marked mutilations in 25 of the latter variety in which tuberculoid lepra reactions had been common sulphones prevented the recurrence of such reactions, and the cutaneous lesions disappeared or reverted to an uncharacteristic appearance although nerve lesions were uninfluenced. Similar results were observed in 200 dispensary cases but the skin lesions in most of them were not completely cleared up after 12 months treatment. They should also be treated early.

The uncharacteristic cases are still difficult to evaluate because 40 per cent cleared up spontaneously and no cases have become lepromatous. In lepromatous cases bacteriological findings in nasal smears showed a reduction of positive results to only 2 per cent after treatment with presumably much reduced infectivity but in advanced lepromatous cases scarification of the nasal mucous membrane gave positive results in 102 out of 879 smears or 11 per cent. In skin lesions the results were less favourable for in 64 biopsy specimens of residual lepromas only 10 per cent were negative, although morphological changes and reduced numbers of bacilli were frequent. Sections of the sites of old lesions were negative in 50 per cent and in 45 per cent only small numbers of morphologically modified bacteria were found. Histological improvement was common with a tendency to tuberculoid structure. The intravenous administration is preferred in all acute and ocular cases and in the occurrence of erythema nodosum. No serious accidents have occurred in four years.

ERICKSON P. T. & JORANSEN F. A. Bone Changes in Leprosy under Sulfone Therapy. *Internat. J. Leprosy* 1948 Apr-June v. 18 No. 2, 147-54, 8 figs on 4 pls. [10 refs.]

Bone changes in leprosy depend on neurotrophic disorders due to nerve involvement of a chronic nature, so only slow response to treatment could be expected during the five years of this treatment in Carville of 82 patients with promin disease or promirole. Tables record the duration of the sulphone treatment, the bone changes in the hands and feet over a five-year period, and the neural symptoms and their probable response to treatment. Previous Carville studies suggest that in lepromatous cases there are few bone changes except in the form of cysts and osteomyelitis, and it is significant that these lesions appear to respond best to sulphone treatment. There also appears to result some restraint on further progression of bone absorption, so early treatment is indicated. A follow-up period of ten years likely to be required fully to assess results of this treatment. Four pairs of X-ray plates are included.

SAGHER, F & FRANCO, S El efecto de los rayos limite sobre las infiltraciones leprosas II Informe sobre el intento de influenciar la facies leonina y la ulcera perforante plantar por mediación de radiaciones roentgen de larga longitud [The Effect of X-Rays on Cutaneous Lesions and their contained Bacteria in Leprosy] *Rev "Fontilles"* Valencia 1948, July, v 2, No 2, 166-71, 16 figs on 5 pls

The treatment by X-rays lasted usually for 6-12 months; but changes were observable in 2-3 months Smears were made from the tissue during the course and biopsy specimens were taken periodically from the same spot each time, so that strict comparisons could be drawn Nine patients with nodular leprosy were subjected to the treatment, nodules and infiltrations of the hands and face and ulcers of the foot The improvement was quite distinct and in some instances the lesions actually disappeared Photographs taken before and after the course of treatment show the changes quite clearly Strange to say, however, smears from the lesions showed no significant changes in the bacterial content in many, though one *might* find disappearance of the leprous tissue accompanied by reduction in the number of bacteria and changes in their form Patients kept under observation for as long as 4 years after the treatment was begun did not, except in one case, show any relapse in the area radiated, if the dose had been fairly large (5,000-10,000 r), but new lesions might appear in their vicinity and elsewhere

APARISI JIJON T Nota previa del tratamiento de los lepromas recidivantes, episclerales y esclerales [The Treatment of Relapsing Episcleral and Scleral Lepromata a Preliminary Note] *Rev "Fontilles"* Valencia 1948, Jan, v 2 No 1 46-7

HINGSON, R A, JOHANSEN, F A, ERICKSON, P T, ELLIOTT, D E, MEYER W H, FITE, G L, WOLCOTT, R R & PREJEAN, B H Preliminary Study of the Hypospray for Parenteral Therapy in its relation to the Management of Leprosy *Internat J Leprosy* 1948, Apr-June, v 16, No 2, 173-8, 7 figs on 2 pls

This paper describes and illustrates an instrument for injecting solutions (promin, procaine, antibiotics, etc) under a pressure of 125 pounds of spring pressure through an orifice 0.003 of an inch in diameter—the size of a 26-gauge hypodermic needle and approximately that of the proboscis of a mosquito—the solution leaving the orifice at a velocity of approximately 600 miles an hour, or about twice the necessary pressure for such a fine jet to pierce the skin and subcutaneous fat The advantages claimed for it are absence of or greatly diminished pain on injection of various solutions, sterilization is unnecessary on account of preparation of the "metapules" which hold the solution, and painlessness prevents children fearing the injections The time of multiple sterilizations is saved, so that prolonged daily injections of various preparations including promin is facilitated It has also been used at Carville to afford instantaneous relief of nerve pains of leprosy by injection of procaine The new instrument is not yet on general sale as further improvements are expected, packing of the drugs in the metallic containers is at present only done by the Scherer Corporation, but it is hoped to be able to make it a reasonable cost, as a single instrument will outlast several syringes and many needles Two plates illustrate the instrument

- I. **LEPROSY REVIEW** 1948, July v 19 No 3 86-109 **Fifth International Congress of Leprosy** [Abstracts of Proceedings and Report of Committee.]
- II. **INTERNAT J LEPROSY** 1948 Apr-June v 16 No. 2, 235-317 **Summaries of Papers presented to the Fifth International Leprosy Congress, Havana, Cuba, Apr 8-11 1948.**

I. This account records the conclusions of the committees which studied the evidence under different subjects in the various papers read at the Congress. It has been written by Dr G. A. RYKIE who attended the meetings.

Report of the Committee on Therapy—Advances have been made owing to the use of sulphones and of increasing doses of hydnicarpus oil. The former are of great value in lepromatous cases of an advanced or moderately advanced type especially with respect to lesions of the nose throat and eyes, and they are the present drugs of election. The actions of promin, diasone and sulphetone are equal bacteriostatically and the following dosage is advised. Promin is given intravenously each day for one to three months in doses (for adults) increased after one or two weeks from 2 gm. in 5 cc. of solution up to 12.5 cc. and resumed after one to two weeks rest. Diasone is given orally on weekdays in doses of from 0.3 gm. daily increased by 0.3 gm. each week for three weeks and subsequently to 1.6 gm. daily if well tolerated, with 1 to 2 weeks rest every two months. Sulphetone may be used by injection or orally to produce a concentration in the blood of 5 mgm. per 100 cc., for which purpose daily doses of 3 to 6 gm. orally are required in adults, beginning with 0.5 gm. three times a day increased by 0.5 gm. per day to the required amount. In children 1.5 to 3 gm. daily are recommended. A period of rest is advised after six months. Any resulting anaemia is treated by iron, vitamin B complex, liver extract and thiamin chloride. The occurrence of erythema nodosum oriritis indicates temporary suspension of sulphones. Haemotoxic or renal reactions should be watched for.

Many workers have found large and regular dosage of hydnicarpus oil or its derivatives to be effective such as 15 to 25 cc weekly raised if it is well borne to 40 to 50 cc. per week. Some workers consider that the drug should be continued during reactions unless the eyes are affected. A period of rest may be advisable after every three and a half months treatment. Supplementary surgical and other methods should also be used. Further research is advised on antibiotics and other new preparations such as streptomycin and para-amino salicylic acid and on combinations of drugs. Sulphones should only be sold on medical prescription and it is hoped that their cost will be reduced.

Report of the Committee on Epidemiology and Control.—The difficulties of epidemiological enquiries are first stressed and the statistical control of clinical data collected over a number of years is advocated. A modified life table method should, if possible, be used to enable the magnitude of the problem in each area to be determined. In order to obtain uniformity various terms are defined. Under the heading of control, the Committee advised leprovaria of the agricultural colony type with separation of the infectious and non-infectious cases, and sanatoria for patients with personal financial resources within easy communication of an urban centre and not on a small island. The sod should allow of agricultural activities and the capacity should not exceed 1000 patients. Other recommendations are dispensaries and out-patient clinics selection of cases for isolation and treatment control of unisolated cases removal of children of infective patients to preventoria the control of contact with re-examination every six months for five years from the last contact with an infectious case and nurseries for newly born infants of leprosy patients—all measures which have been repeatedly advised for a number of

years Legal enactments should embody only general principles and regulations should be made by experts Education of medical students and the general public on leprosy is required The disease is frequently curable and only "open" cases need be isolated The word "leper" should be avoided as much as possible An appendix of recommended indices is added

Report of the Committee on Classification and Nomenclature—In an attempt to reconcile apparently discordant systems, classification should be based on clinical, bacteriological, immunological and histopathological data in diminishing order of availability The "polar" forms are lepromatous and tuberculoid, to which should be added indeterminate (undifferentiated) or I forms The degree of severity, manner of evolution, localization, morphology and clinical form should also be recorded

Report on the Words "Leper" and "Leprosy"—Cases should be designated "leprosy patient" and the term "leper" abandoned, but the former term should not be discarded A social assistance programme should include provision for healthy children, assistance of families of leprosy patients, education of the patients and their rehabilitation on leaving leprosaria

ii This consists of summaries of 153 papers and titles of 43 other papers presented at the Havana Congress, classified by subjects essentially as in the session programmes and for the most part in the language of presentation The language distribution is Spanish 66, English 55, French 22, Portuguese 10

SOARES, J A Os dispensarios na profilaxia de lepra (Considerações referentes ao serviço de profilaxia da lepra, no estado do Espírito Santo, de 1927 a 1945) [Dispensaries in Leprosy Prophylaxis as exemplified in Spirito Santo, Brazil, between 1927 and 1945] *Rev Brasileira Leprologia* S Paulo 1948, Mar, v 16, No 1, 35-51, 5 charts [17 refs]

Professor de Souza-Araujo more than a quarter of a century ago stated the aims of dispensaries in dealing with leprosy, which included a census of sufferers from leprosy, epidemiological inquiries in leprosy foci, selection of cases for ambulatory, domiciliary or hospital treatment, etc

A Leprosy Prophylactic Service was started in 1927 under the direction of Dr Pedro Fontes, in 1928 a census was taken and by 1931 290 cases had been noted By 1934, there were 8 dispensaries established in places where the incidence was highest In 1936, a plan was evolved for centralizing and controlling the activities of these dispensaries, for attracting the infected, the suspected and their contacts for examination, re-examination and treatment, an Assistance Service for the patient and his dependants, for getting hold of vagrant patients and for educating the children A colony was established in 1937 and two years later a home for the healthy children of leper patients Next follows an account of the staffs of these several dispensaries and a table showing the distribution of 1,000 patients in the eight dispensary districts, of these, 256 are interned Apart from the dispensaries at fixed places there is an itinerant service which pays periodic visits to other places and makes epidemiological investigations

EICHBAUM F W Potenciação da ação vermífida do hexylresorcinol por detergentes. Experiências *in vitro* com *Ascaris* de porco. [Effects of Detergents on the Vermifugal Activity of Hexylresorcinol. *In vitro* Experiments with Hog *Ascaris*.] *Mém. Inst. Butantan*. 1947 v 20 203-15. 1 fig English summary.

Three sets of tests were undertaken (1) The vermifugal action of hexylresorcinol alone of the detergents alone and of the combination of the two in physiological saline and in Tyrode's solution. (2) The synergistic activity of sodium anacardate and of the anacid fraction of cashew nut oil. By the "anacid fraction" is implied that part of the oil which remains after precipitation of anacardic acid by hydrosulfide of lead its chief components are cardol and anacardol. (3) The influence of the presence of mucus on the vermifugal action of hexylresorcinol alone and with detergents. The following substances were used in the tests 5 per cent. solution of hexylresorcinol 5 per cent. aqueous solution of sodium anacardate the anacid fraction of cashew oil (see above) 10 per cent anacardol in alcohol the oil itself, 10 per cent. in alcohol sodium tetrahydro-anacardate 5 per cent. in water and the following sodium salts ricinoleate oleate linoleate stearate and palmitate all in aqueous solution the first two 5 per cent. the third 1 and 2.5 per cent., the others 1 per cent. The effect on the worms *Ascaris* *swis* was watched through a glass-fronted apparatus.

The vermifugal effect of hexylresorcinol is enhanced by detergents in certain proportions but if the latter are high the effect is in part at least inhibited. Sodium anacardate anacardol, the anacid fraction and a tincture of the oil enhance the action especially the first and third of these. The first and last are fairly powerful vermifuges themselves.

In Tyrode's solution, the effectiveness is lowered, owing to the formation of insoluble Ca and Mg salts. Mucus inhibits the anthelmintic activity of hexylresorcinol, but very slightly if detergents are present. H Harold Scott

LEÃO, A. T & EICHBAUM F W Ação vermífida do óleo de cajá (*Anacardium occidentale*) e derivados. Experiências em cães. [Vermifugal Activity of the Cashew Oil (*Anacardium occidentale*) and Derivatives. Experiments in Dogs.] *Mém. Inst. Butantan* 1947 v 20 15-30 English summary

More than a century ago in 1806, DUCHENNE recorded the use of Cashew oil, *Anacardium occidentale* in helminthiasis and Eichbaum (*Nature* 1944, Apr 6, 449) the vermifugal action *in vitro* of anacardic acid, one of the constituents of the oil. The oil is contained in the pericarp. The present paper reports the results of giving the oil to infested dogs. Twenty-six dogs were used for these experiments and the infections were by *Incystosoma caninum* *Tetracera uris*, *Trichuris vulpis* and *Dipylidium caninum*. Four preparations of the oil were tested sodium anacardate an emulsion containing 20 per cent. of the pure oil and the crude oil itself, anacardic acid, and a mixture of cardol and anacardol. Tables are presented showing the details of all the experiments carried out, but these may be summarized by saying that the best results were

obtained with the pure oil. The drug was given in gelatin capsules each containing 1 gm, or by stomach-tube, and in doses from 2.5 to 8 gm according to the weight of the animals. The results were confirmed by autopsies on the dogs treated. *A. caninum* was reduced by 96.8 per cent, *Toxocara canis* was completely eliminated after a single dose, *Trichuris vulpis* reduced by 77.3 per cent. There was no evidence of any pathological lesion of the stomach or intestinal mucosa, nor of the liver or kidneys, elimination takes place by the kidneys and the larger bile ducts. H. Harold Scott

GOODLIFFE, F. A. & BLAIR, D. M. Hatching Speed of Schistosome Miracidia. [Correspondence] *Trans Roy Soc Trop Med & Hyg* 1948, Sept v 42, No 2, 205

It is difficult to detect the actual emergence of miracidia of *S. haematobium* from their egg shells and the speed of this would appear to be very great.

The authors in Southern Rhodesia, studied the individual "frames" of a cine film exposed during the act of hatching. An intact egg was found in one frame and an empty split egg shell, with the miracidium a short distance away, was found in the next. The act of emergence must have coincided with the instant when the film was not exposed to the light transmitted through the slide, namely the 1/48th of a second while the shutter was closed. The hatching took place at room temperature (about 72°F). H. J. O'D. Burke-Gaffney

SHORT, R. B. Hermaphrodites in a Puerto Rican Strain of *Schistosoma mansoni*. *J Parasitology* 1948, June, v 34, No 3, 240-42, 1 fig

Short records the finding of 13 hermaphroditic males of *S. mansoni* out of 35 which he examined. The worms were collected in Porto Rico, but the host is unknown. The female reproductive system in some of the specimens was more completely formed than in those described by VOGEL [this *Bulletin*, 1948, v 45, 93], whose examples appeared to lack vitelline ducts, oötype, Mehlis' gland or a female genital pore. Some of the Porto Rican specimens possess oviducts, oötype, Mehlis' gland, short uteri, main vitelline ducts and vitellaria in different stages of completeness, in addition to well developed ovaries. In three specimens a female genital pore is present. Where this is easily visible, the male and female ducts unite at or close to the opening which thus may be regarded as a common genital pore. In one specimen, which is figured, there is a complete set of female organs which, however, are not quite typical and the vitellaria are not well formed. No eggs were present either in the uterus or oötype of any specimens, but in one the vitelline ducts contained a few vitelline cells. The seminal vesicles rarely contained spermatozoa, and these were usually in very small numbers. In four worms, the testes were reduced (in two cases, to three in number). J. J. C. Buckley

PAPIRMEISTER, B. & BANG, F. B. The In Vitro Action of Immune Sera on Cercariae of *Schistosoma mansoni*. *Amer J Hyg* 1948, July, v 48, No 1, 74-80, 4 figs on 1 pl

Using sera from monkeys experimentally infected with either *S. mansoni* or *S. japonicum* and sera from three human patients, each infected with either *S. mansoni*, *S. japonicum* or *S. haematobium*, the authors demonstrated the formation of a precipitate around the cercariae of *S. mansoni* acquired from the snails *Australorbis glabratus*.

Cercariae were exposed, within 1 hour of being concentrated or a maximum of 3 hours after leaving the snails, in a physiological saline suspension and a

1 in 2 dilution of serum. At room temperature the precipitate was formed around the tail of the cercaria in about one hour after which movement became sluggish, and within 3 hours the body was also surrounded. A precipitate was formed with control cercariae in normal sera and these survived longer and in contrast with the cercariae in the immune sera they usually shed their tails. In a very high percentage of the cercariae exposed, the precipitate was formed in both the monkey and human immune sera. The highest titres and most extensive precipitate were produced by two monkeys recently infected with *S. mansoni* and by the recently infected patient (*S. japonicum*). The lowest titres were obtained in 8 monkeys infected with *S. japonicum* which were lightly infected and whose infection was of 2 to 2½ years duration. The sera of only 3 of these 8 monkeys produced precipitate without the addition of guinea-pig complement (unheated guinea-pig serum diluted 1 in 10). Heating the positive sera in a water bath at 56°C. for half an hour destroyed the ability to produce precipitate but the addition of guinea-pig complement restored it in every case.

LEVINE, M. D. GARZOLI R. F., KURTZ, R. E. & HILLOUGH J. H. On the Demonstration of Hyaluronidase in Cercariae of *Schistosoma mansoni*. *J Parasitology* 1948 Apr., 34 No. 2, 158-61 ? figs.

The fact that hyaluronidase an enzyme capable of disaggregating and depolymerizing hyaluronic acid, has been demonstrated in numerous bacterial organisms and has been shown to be a mechanism whereby these organisms spread in skin, suggested the possibility that this enzyme might well be involved in the mechanism of cercarial penetration of skin. A technique is described in which the hyaluronidase activity of cercariae of *S. mansoni* in suspensions prepared with sodium hyaluronate was tested. Considerable activity was demonstrated, although there was no relationship between the number of cercariae used and the activity.

The authors do not hold that this ability of *S. mansoni* cercariae is entirely responsible for the phenomenon of cercarial penetration and remark that collagenase or proteolytic enzymes might also be present but these have not yet been investigated.

J J C Buckley

GELFAND M. Bilharzial Disease of the Bladder as determined at Autopsy with particular reference to its Diagnosis by Mucosal Snips. *Amer J Trop Med* 1948, July & Aug. No. 4 563-6.

The author classifies the macroscopic lesions of the bladder found at autopsy in *S. haematobium* infections into (1) whitish tubercles varying in number and from 0.5 mm. to 2 mm. in size seen mostly on the fundus (2) greyish-yellow or reddish brown "sandy" patches of similar distribution, but later in appearance and (3) reddish warty papillomata, seen usually in the fundus and apex in about 8 per cent. of cases. It refers to the general impression held by many authorities that macroscopic lesions may be expected if ova are deposited in the bladder and that a normal naked-eye appearance of the bladder excludes schistosomiasis.

In the present study the author in S. Rhodesia, examined the bladder macroscopically at autopsy in 50 consecutive cases of vesical schistosomiasis and then digested each whole bladder in 10 per cent. caustic potash at 60°C. for 10 hours. The centrifuged digest was then examined for ova. (In S. Rhodesia the disease may be considered to be well established by the time adult life is reached—the patients in this case were Africans of 20 to 50 years.)

In the 50 cases, 34 (68 per cent) showed macroscopic lesions, as defined above in 16 (32 per cent) no macroscopic abnormality was found, but ova were detected, on digestion of the specimens. It is thus clear that the bladder may be diseased, even if cystoscopy shows no abnormality.

The author then refers to the work of OTTOLINA & ATENCIO [this *Bulletin*, 1944, v 41, 945 and HERNANDEZ MORALES & MALDONADO [*ibid*, 1947, v 44, 330] on rectal biopsy in the diagnosis of *S. mansoni* infections. He himself has been able to demonstrate positive biopsy snips in most of those passing ova in their stools, he has also been able to diagnose *S. haematobium* by biopsy in about 40 per cent of cases [paper in publication].

He also took snips about 2-3 mm in size from 10 bladders, apparently free from lesions macroscopically. Nine of these were positive for *S. haematobium*. He therefore recommends that should a bladder appear to be normal on cystoscopic examination for evidence of schistosomiasis, a snip of the mucosa should be examined for ova, since the disease cannot otherwise be excluded. [The author refers to a paper by himself in 1947, now under publication but there is no reference to the paper by MEESER, ROSS & BLAIR, also in *S. Rhodesia*, on the diagnosis of rectal schistosomiasis, which includes rectal biopsy (this *Bulletin*, 1948, v 45, 794)]

ERFAN, M. Pulmonary Schistosomiasis. *Trans Roy Soc Trop Med & Hyg* 1948, Sept, v 42, No 2, 109-13 [14 refs]. Discussion 113-16 [MANSON-BAHR, P., TIDY, H., DAY, CHESTERMAN, C C., ALVES, ERFAN]

Lung infection in schistosomiasis occurs early, when the cercariae are migrating, and later if there is lodgement of ova and worms in the lungs. In Egypt, 60 to 70 per cent of the population harbour schistosomes, of these a third suffer from secondary pulmonary schistosomiasis. The disease is one of agricultural workers, its greatest incidence is in children and young adults, males preponderating.

Ova and worms reach the lungs embolically from veins in the urinary or intestinal tracts, they travel by the internal iliac veins, and through the porto-caval anastomoses respectively. *S. haematobium* ova are more commonly found in the lungs than those of *S. mansoni*. The ova cause two types of lesions, parenchymatous and arterial. On escaping from the lung arterioles into the adjacent tissue they are surrounded by histiocytes and eosinophiles, then by lymphocytes and a few giant cells, and fibroblasts finally form a nodular scar. These parenchymatous lesions occur around the bronchioles and alveoli, but cause little change in the finer structure of the lungs. The arterial lesions, usually due to the ova of *S. mansoni*, though less common, are more serious. They are caused by the passage of ova through the arteriolar walls, with scarring and atresia or occlusion of the vessels. Occluded vessels may be canalized, with the formation of angiomatoids. If the vascular lesions are numerous the right ventricle dilates, hypertrophies, and finally fails. In the early stage, miliary bilharzial tubercles can be seen microscopically in clusters, or arranged in lines, around the thickened arteries. Later the tubercles vanish, and only the thickened dilated vessels are to be seen. The pulmonary artery and its primary branches may be greatly dilated, and their walls show atheromatous changes. In their lumina there may be ante-mortem thrombi. The right ventricle is dilated and hypertrophied, its wall being 1 cm or more in thickness. There may be schistosomes in vessels in the lungs though they are harmless when alive, on dying they cause a necrotic focal pneumonia evident, at postmortem as opaque white areas of consolidation 0.1 to 0.5 cm in diameter. The arteriolar involvement gives rise to a condition resembling Wertheim's disease, or primary pulmonary endarteritis, but cyanosis, the most

striking feature of this disease is noticeably absent in pulmonary schistosomiasis until the right ventricle fails. Radiologically, in early cases, the nodules can be seen along the ramifications of the pulmonary artery. Later there is increase in number, the hilar shadows increase, and the subaortic notch is obliterated. In very advanced disease the hilar shadows are further increased, and the pulmonary artery and conus are greatly enlarged, reaching aneurysmal size and marking the aorta. The heart develops the appearance of *cor pulmonale*.

A specific diagnosis of pulmonary schistosomiasis rests on discovery of ova in the sputum but they are rarely found. Establishment of the presence of the primary infection is essential and clinical examination of the lungs is of little help. Clinical and radiological examination of the heart is important. Eosinophilia is more pronounced in cases with lung involvement.

Two per cent. of those suffering from schistosomiasis die from right ventricular failure as a result of pulmonary arterial disease. This failure occurs late, its causation being mechanical rather than myocardial. Treatment with antimony should be given early before there is enlargement of the right ventricle. In cases with right ventricular failure, antimony is contra-indicated. The heart failure is treated along the usual lines with digitalis, venesection, and mercurials.

In the discussion which followed the lecture Sir HENRY TUDY praised the advances made by the Egyptian workers in the study of schistosomiasis during the last 20 years. The recognition of pulmonary and hepatic bilharzial disease was largely due to them. Ayerza's disease, according to the textbooks, is characterized by deep cyanosis due to sclerosis of the pulmonary artery and probably is syphilitic in origin. The best recent description of the pathology of the condition has been given by CHERRY in America. There appears to be no essential difference between his illustrations of the arterial changes and those reproduced from cases of pulmonary schistosomiasis in Egypt. Many cases of Ayerza's disease come from mining areas in high altitudes in S. America. On bringing these patients to low altitudes (such as obtain in Egypt) the cyanosis diminishes. There is no adequate ground for considering syphilis a causative factor in this condition and the name should be restricted to the particular syndrome in S. America, and not be applied to every case of pulmonary arteritis with death in cardiac failure.

The intensive courses of antimony treatment advocated by Blair and Alves should be used with caution. There have been reported some bad reactions in S. Africa and even more severe in Egypt. The S. African patients, apart from their schistosomiasis, were healthy but in Egypt hookworm and other infections are ubiquitous.

Prof. DAY referred to LOOKS's fear that when specific treatment for schistosomiasis was found the resultant verminous thrombophlebitis might be worse for the patient than the parasitic infestation. He had observed a remarkable degree of necrosis and infiltration around dead worms in the liver, a condition which resembled that depicted in recent papers on filariasis. Similar reactions may well occur in the lungs. The proportions of cases of lung involvement due respectively to embolism of ova and to actual worm infestations have yet to be decided. A pulsating shadow in the hilar region around the heart, if it were to be seen on screening and were due to incompetence of the pulmonary valves might be of diagnostic significance.

Dr. C. C. CRESTHORN referred to the complications, including pulmonary symptoms due to *S. intercalatum* infestations to which he drew attention 25 years ago. He agreed with the opinion that there are possible dangers in too energetic treatment with tartar emetic for example pulmonary tuberculosis may be activated.

Mr ALVES stated that after concentration with KOH very scanty ova in the sputum may be revealed. There may be racial differences in the susceptibilities of Bantu and Egyptian to antimony, but schistosomiasis in Egypt is clinically a much more severe disease than elsewhere in Africa. The radiological recognition of pulmonary schistosomiasis in S Rhodesia is complicated by the prevalence of silicosis and tuberculosis, both of which it resembles.

Prof ERFAN in reply said that the intensive antimony treatment in Egypt produces severe, and often serious, general reactions. He agreed with DAY that hilar pulsations may be seen in cases of interatrial septal defect, but they are not marked in bilharzial pulmonary arterial disease as the vessels are atheromatous and rigid.

HASHEM M. The Incidence of Non-Schistosomal Forms of Hepatic Cirrhosis in Egypt. Their Morphology and Pathogenesis. *J Roy Egyptian Med Ass* 1948, Mar-July & Aug, v 31, Nos 3, 7 & 8, 222-9, 541-55, 635-50, 17 figs on 9 pls [32 refs]

MAUSS H. Ueber basisch substituierte Xanthon- und Thioxanthon-Abkömmlinge. Miracid, ein neues Chemotherapeuticum [Miracid, a New Chemotherapeutic Agent]. *Chem Berichte* 1948, Jan, v 81, No 1, 19-31 [Refs in footnotes]

CAWSTON, F G. Criteria of the Cure of "Bilharziasis". *J Trop Med & Hyg* 1948, Sept, v 51, No 9, 184

The author lists certain points to be observed in assessing cure of schistosomiasis [though not giving much clinical or any statistical evidence in support of them]. Failure to hatch is no evidence that female adult worms are dead and treatment should be continued for a week after ova have ceased to appear. If total dosage is inadequate, ova tend to reappear at the end of six weeks.

The author has cured a case in 22 days with a total of 50 cc of anthiomaline in doses up to 4 cc intravenously five times a week, without causing more than the slightest cough. He considers this to be a minimum period of cure.

Degeneration of adult worms may be estimated by the gradually increasing proportion of dead and degenerating ova in the excreta, after 10 days. The first sign of drug effect is a slightly increased transparency of the egg shells, associated with increased activity of the contained miracidia or the presence of ill-formed ones. It is stated that some ova later are seen to be black without trace of a miracidium, especially where antimony or benzoic acid is being administered. This the author attributes to the entry of blood through the egg shells damaged by the drug. A further indication of the death of the adult worms is a temporary rise in the eosinophile count a few days after the start of treatment; this nearly always returns to normal two months after the death of all the adult parasites.

FAUST, E C & BONNE, C. Mammalian Blood Flukes of Celebes. *J Parasitology* 1948, Apr, v 34, No 2, 124-31, 12 figs [14 refs]

The circumstances of the discovery of a focus of *Schistosoma japonicum* and of *Echinostoma lindoensis* in 1936 in the Lake Lindoe region of the Celebes [this *Bulletin*, 1938, v 35, 218] are reviewed by the authors. In the present communication the earlier data are amplified and more detailed morphological facts are presented. In the advanced stages, schistosomiasis in the inhabitants of Lake Lindoe villages presents the classical clinical picture of splenomegaly, hepatic cirrhosis, ascites and emaciation. Adult worms obtained from human, canine and cervine hosts were examined in detail and shown to be morphologically identical with *S japonicum*. A collection of snails made in the Lake Lindoe region contained no *Oncomelania*.

Reference is also made to an expedition in 1941 to Lake Po-o 100 kilometres to the south-east of Lake Lindoe [this *Bulletin* 1947 v 39 628, 629]. No human, or animal infections with schistosomes were found there nor were any snails of the genus *Oncomelania* discovered, but from a single specimen of *Lymnaea* sp. furcocercous cercariae were obtained. The morphology of these is described and also that of immature flukes obtained as a result of exposing rats and mice to the cercariae. Although these worms are believed to belong to the genus *Schistosoma* rather than *Schistosomatium*, it is concluded that they are not *S. japonicum*.

J. J. C. Buckley

LI, Fu Ching Zur Frage der Schistosomiasis Japonica und ihrer Bekämpfung in China. [*Schistosomiasis japonica* and the combating of it in China.] *Chinese Rev. Trop. Med.* 1948, Jan. v 1 No. 1 15-28 2 figs. (1 folding) (23 refs.)

This article is divided into three main sections. The first speaks of the worm itself its discovery, life-history and its presence in China. The second of its epidemiology in China, especially in Kiangsu and Chekiang provinces and in 9 districts, but hardly any figures are given merely averages and extremes for certain areas and sub-districts and the same for the percentages of infected *Oncomelania* found, varying from 1 to 16 the totals examined on which these percentages are based are rarely stated.

Among 37 districts more than half the people are infected (55.6 per cent) in the heavily infected and as much as 39.6 per cent, in the more lightly infected. Of over 12 million inhabitants of these districts 80 per cent, are peasants and 47.4 per cent, of them suffer from schistosomiasis a much higher proportion than in Japan itself where the author states, among 1½ million persons (where?) only 5.3 per cent, are infected. As regards sex the inferences drawn have little validity because the numbers are small of 423 adult males, 153 were infected (36.1 per cent.) of 86 women 12 (14 per cent.) of 81 boys 18, and of 19 girls 5 were infected also the figures of the females are erroneous.

from modesty" they are averse to consulting a doctor. The third section deals with the measures to combat the disease. These are on the usual lines drying the canals to kill the snail vector the use of toxic substances in the water proper provision for excreta disposal, treatment of patients and explanatory propaganda among the people.

H. Harold Scott

PITNER G. McNAMARA W. L. & GODDARD F. M. Parasitologic Studies of World War II Veterans, with special references to Schistosomiasis Japonica. *Amer. J. Clin. Path.* 1948 Aug., v 18 No. 8, 833-4

In order to detect asymptomatic and sub-clinical schistosomiasis the stools of 130 patients in a Veterans Administration hospital who had definite histories of exposure to fresh inland water in an area endemic for schistosomiasis (*japonicum*) were examined repeatedly by five different methods, namely —

- (1) Direct smear pieces of mucus being selected if possible
- (2) Acid-ether concentration technique
- (3) Sedimentation after comminution in 25 parts of 0.5 per cent. glycena in tap water and filtration through wet gauze the process being repeated several times.
- (4) Egg hatching technique with examination for miracidia with a hand lens.
- (5) Combined screening and sedimentation technique by filtration through 100-mesh wire cloth (opening 150µ) and then through 400-mesh (openings 37µ)

In addition, Faust's zinc sulphate centrifugal flotation method for protozoa and other ova was used as a routine

The findings were as follows — *Schistosoma japonicum* ova were found in 5 patients, hookworm ova in 44, *Trichuris trichiura* ova in 34, *Ascaris* ova in 3, *Hymenolepis nana* ova in 1, *Trichostrongylus* ova in 3, *Strongyloides* larvae in 1 and *Entamoeba histolytica* in 18

L E Napier

TARR, L Effect of the Antimony Compounds, Fouadin and Tartar Emetic, on the Electrocardiogram of Man, a Study of the Changes encountered in 141 Patients treated for Schistosomiasis *Ann Intern Med* 1947, Dec, v 27, No 6, 970-88, 5 figs [13 refs]

Heart failure and death have been reported as a result of trivalent antimony injections, but no significant electrocardiographic changes had been reported prior to MAINZER and KRAUSE's paper [this *Bulletin*, 1940, v 37, 487]

The present study was made on a series of 200 patients with schistosomiasis (*japonicum*), service men infected in Leyte. A preliminary report on 66 of these cases has already been published [this *Bulletin*, 1946, v 43, 657] "The first 141 patients to be treated form the basis of this report" The readings were taken under standard conditions, one hour after an injection, at different times during the course of injections, e.g., after 5 ml, 45 ml, 65 ml, 80 ml, 105 ml, of 6.0 per cent fouadin and after 80 ml, 248 ml and 320 ml of 0.5 per cent tartar emetic, but some variations were made and additional readings were taken in special cases. With the preliminary controls, a total of 900 electrocardiograms were taken and read by one observer.

The alterations were for the most part confined to the T-waves. Changes were observed in 133 patients of whom 98 per cent showed involvement of 3 or 4 leads. Three-plus or four-plus changes occurred in 4 of 48 patients on fouadin and in 30 of 98 patients on tartar emetic. These changes were defined by the author as follows —

"Three plus change was a continued decrease in the height of the T-waves to extremely low voltage or isoelectric levels in three or more leads, accompanied by a slight negativity of the terminal portion in one or more of the leads. The summits of the waves presented no sharp angles, but were rounded or flattened."

"Four plus change represented an alteration from positive T-waves to sharply negative or even cove plane T-waves in three or more leads, with low voltage in the remaining lead."

Generally, the changes varied in degree with the total dosage, but there were considerable individual variations, in some cases changes were noted after minimal dosages, whereas in others no changes were noted with large dosages. If however an alteration was noted early in the course, this alteration either remained throughout or more usually was intensified. Four-plus alterations were noted after 176 ml, 200 ml, 320 ml or 416 ml of tartar emetic and after 80 ml of fouadin. Greater alterations were observed after tartar emetic than after fouadin, but the alterations were of the same nature. Some change was noted in every patient with the former drug.

When a second course of injections was given the alterations occurred again and were usually of the same degree. Further, if a tartar emetic course was given after an initial fouadin course, the alterations were of the same degree or were intensified.

The changes were reversible. After the completion of the course they increased in some cases for a few days and then decreased steadily and were absent 30 to 60 days later in 90 per cent of cases, in the remaining 10 per cent. minimal alterations still remained.

The changes in their most marked form might have been interpreted as showing evidence of myocardial degeneration. There was in no case any clinical evidence of cardiac dysfunction.

The author concluded that the alteration was brought about by the deposits of antimony in the heart muscle. "The changes induced were of such definite and distinct pattern that in the more marked alterations they may, within the limitation of our present knowledge be recognised as a specific effect of antimony"

L. E. Nafie

OLSEN, O. W. Wild Rabbits as Reservoir Hosts of the Common Liver Fluke, *Fasciola hepatica* in Southern Texas. *J. Parasitology* 1948 Apr v 34 No. 2, 119-23 [18 refs.]

For the purpose of estimating the importance of wild rabbits as natural disseminators of the common liver fluke post mortem examinations were carried out on 309 jack rabbits *Lepus californicus merriami* and 24 cottontails, *Sylvilagus floridanus* subsp. which were collected in the Gulf Coast region of Texas. Infection with *Fasciola hepatica* was found in 32 per cent. of the jack-rabbits and in 20.8 per cent. of the cottontails. The flukes were usually located in the common bile duct where they caused extreme hypertrophy of the duct walls, resulting in extensive malformation. The number of flukes in the jack-rabbits ranged from 1 to 7 per animal. 3 flukes were found in one cottontail.

The literature dealing with records of *F. hepatica* in rabbits and hares is reviewed and the rôle played by these animals in maintaining the infection and disseminating it to domestic ruminants is discussed.

J. J. C. Buckley

DA FONSECA, F. & DE AZEVEDO, J. F. Um caso humano de fasciolose hepática [A Human Case of *Fasciola hepatica* Infection.] *Ana. Parasit. Hum. et Comparat.* 1948 v 23 Nos 1/2, 18-22.

The authors discuss the world incidence of *Fasciola hepatica* infections in man and quote a number of figures taken from the literature. They are not aware of any reported cases of this infection in continental Portugal or its neighbouring islands [but cases have recently been described from Spain see this *Bulletin* 1948 v 45 197]. They then describe in detail the case of a man of 31 born and bred in Funchal, Madeira, who had paid his first visit to the mainland in November 1947. He then gave a history of one year's gastrointestinal disturbances with loose stools twice daily, backache, malaise, night sweats and abdominal fulness. On examination, the abdomen proved to be full and tender especially along the course of the colon. The liver was a little hard and tender and the spleen was enlarged. The blood picture showed a persistent eosinophilia of 34 to 50 per cent. On the ninth day of observation the patient developed an urticarial eruption on the hand, neck and abdomen. Laboratory examinations were largely uninformative except that in the stools *E. histolytica* (vegetative forms) were found, together with eggs of *Fasciola hepatica*, *Ascaris lumbricoides* and *Trichuris trichiura*. The first named eggs were also found in specimens of bile.

Diagnosis was first suggested by the eosinophilia, which led to the finding of the ova in the stool and bile. The eggs were morphologically typical.

The patient was given to the frequent consumption of raw watercress and lettuce and it is presumed that the former was the likely vehicle of infection.

with metacercariae. This aquatic plant is eaten frequently by the people of Madeira, so that more cases of this infection may arise. The authors consider that a thorough investigation of this question should be made.

They are attempting to establish the complete developmental cycle of the fluke from the eggs passed in the stools and will publish their findings later.

Treatment with emetine has been given, in order to deal with the amoebic infection also. The authors are awaiting the results of this treatment. [Although there is no doubt of the infestation in this case, the question of chemical infection is masked by the presence of the accompanying *E. histolytica* and two other parasites and this same difficulty will complicate interpretation of the results of emetine treatment.]

CACCIAPUOTI, R. Su di una nuova distomiasi umana in Etiopia [A New Distome found in Man in Ethiopia] *Riv di Biol Colon* Rome 1947, v 8, 111-16, 1 fig. [12 refs.]

The trematode described was found by chance when the author was performing an autopsy on a man from Beghemeder, Italian Ethiopia, in 1941. It was present in small cyst-like nodules the size of a pea or a cherry-stone in the small intestine. The mucosa there was congested. The nodules were firm but elastic with contents of serum, pus and blood and many small distomes. None was found in other parts of the intestine, nor in liver, spleen or lung. Specimens were sent to the Director of the Zoological Institute of the University of Naples, who stated that it was a new species of *Pseudoamphistoma*. The author points out its differences from Luehe's first description of this genus and from the known species *P. truncatum* found in the liver by Vinogradoff, and *P. danubiense* found in a cat by Cuerea in 1913. One marked difference is in its having a smooth cuticle. The testes are very large and the mature worm shows a medial laceration due, it is thought, to the rupture of a cyst containing large numbers of ova, whence they may pass to the intestine and are excreted to infest sweet-water fish and crustacea. For more minute details the original should be consulted.

BONNE, C, BRAS, G & LIE KIAN JOE. Five Human Echinostomes in the Malayan Archipelago. *Med Maandblad* Batavia 1948, June 1, No 23, 456-65, 9 figs on 2 pls. [14 refs.]

Echinostome material collected at human autopsies in the Malayan Archipelago before, during and after the war was restudied and five species were recognized. These are described and figured together with notes on their reservoir hosts, life-cycles and transmission.

1 *Euparyphium ilocanum* (Garrison, 1908). Frequently found in the small intestine of mentally abnormal persons in Java and also in normal persons. Over 250 specimens have been collected from a single patient. Main reservoir host, the common field rat, *Rattus rattus brevicaudatus*. First intermediate host, *Anisus convexiusculus*, second intermediate hosts, *Viviparus javanicus*, *V. rudipellis*, *Pala comica*, *Lymnaea rubiginosa*, *Anisus convexiusculus* and *Contradens contradens*.

2 *Echinoparyphium recurvatum* (v Linstow, 1873). Found several times along with the previous species in a rural colony near Batavia. Main reservoir host, *Rattus rattus brevicaudatus*, fowls are also natural hosts. First intermediate host, *Anisus convexiusculus*, second intermediate hosts, *Viviparus javanicus*, *Lymnaea rubiginosa*, *Anisus convexiusculus* and *Contradens contradens*. Feeding experiments gave positive results in pigeons, rats and a cat.

3. *Euparyphium malayanum* (Leiper 1911) In the Malayan Archipelago this has only been met with in Northern Sumatra where 730 specimens were recovered from a 12-year-old Batak girl at post-mortem. Reservoir or intermediate hosts unknown.

4. *Echinostoma revolutum* (Froebel 1897) Seen several times in Java in ducks, fowl and in rats. Twice found as a single specimen in Batavia in post-mortems on Indonesians and 85 specimens were once found in an Indonesian boy of 8 years. First intermediate hosts *Lymnaea rubiginosa* and *Lymnaea convexiuscula* second intermediate hosts *Limporus javanicus* *Palaemon* *Lymnaea rubiginosa* *A. latus* *convexiuscula* *Corbicula striatilis* and other *Cerithium* spp. Feeding experiments positive with pigeons and white rats.

5. *Echinostoma lindoesi* (Sandground & Bonne 1940) Originally described from a heavily-infected tribe on the shores of Lake Lindoe in Central Celebes. In one village 98 per cent of the people were infected. No natural reservoir host has been found, but feeding experiments were positive in rats and in a few cases pigeons and young ducks. First intermediate host *Lymnaea* *lindoesi* Second intermediate hosts *Limporus rubripilis* *Corbicula* *lindoesi* *C. lindoesi* is an important article of diet in the Lake Lindoe villages, where it is cooked in a primitive way.

It is remarked that of the five species occurring in man, only *Echinostoma lindoesi* is specially adapted to the human host: the others are regarded as incidental human parasites whose normal hosts are rats and birds. Regular consumption of snails and mussels is the custom only in the poorer districts where the cooking process is not very thorough. GALLIARD H. Infestation naturelle des batraciens et reptiles par les larves plérocercoides de *Diphyllobothrium mansoni* au Tonkin. [Natural Infestation of Amphibians and Reptiles by Plerocercoid Larvae of *Diphyllobothrium mansoni* in Tonking.] 4 n. *Parasit Humaine et Comparée* 1945, v 21, Nos. 1/2, 23-8.

Sparganosis or infection with plerocercoid larvae of *Diphyllobothrium mansoni* occurs in mammals, birds, reptiles and amphibians in Indo-China. The author investigated the incidence and intensity of the infection in the more commonly infected animals in Tonking. *Rana tigrina* has the highest incidence of 60 per cent. (annual mean) and the infection has a seasonal variation. It is nearly absent in winter, strong in spring and intense in summer. The reason for this is not quite clear. The average number of plerocercoids is 20 per animal in the summer. In November and December it varies from 1 to 4 and in March from 2 to 6. The commonest site of infection is the thigh muscles which is the exclusive site in light infections. The abdominal wall comes next in importance and with increasing numbers of parasites the thorax and back are infected. Visceral infection was encountered only once and on one occasion the parasites were encysted but still viable.

Rana maculata is the commonest amphibian host after *R. tigrina* but its infection is usually light, varying from 2 to 6 parasites. *R. maculata* was not found infected and *B. f. melanostictus* only once out of 116 examined.

Amongst the reptiles, 15 out of 15 *T. opisthotus pictus* were found infected, the parasites being numerous under the skin and in the mesentery. Up to 80 parasites have been found in one animal. On the other hand *Hypsiglena* *melanostictus* is rarely infected.

DESCHIENS, R & BABLET, J Sur deux cas d'enclavement appendiculaire d'anneaux de cestodes [Tapeworm Proglottids in the Appendix an Account of Two Cases] *Acta Tropica* Basle 1948, v 5, No 3, 219-27, 4 figs

The English summary appended to the paper is as follows —

"The study of nine cases of acute appendicitis from natives in French Tropical Africa enabled the authors to demonstrate, in two cases, the presence of proglottids of *Taenia saginata*

"The parasites were enclosed within the lumen of the appendix. It has been found possible to identify them on sections by their characteristic anatomy, and especially by the presence of chalk bodies in the peripheral parenchyma of the worms. The walls of the appendix were inflamed, as also the lymphatic follicles, the latter being on the point of becoming necrotic

"The proglottids appear to have penetrated directly into the appendix, thus assuming the role of an enclosed foreign body"

CRUSZ, H On an English Case of an Intramedullary Spinal Coenurus in Man, with some Remarks on the Identity of *Coenurus* spp Infesting Man *J Helminthology* 1948, v 22, No 2, 73-6, 1 fig & 1 pl

This paper comprises a description and discussion of a coenurus which was removed from the spinal cord of a 14-year-old girl who had developed symptoms of paraplegia. The infection must have been incurred in Britain, probably in Wales during the period 1943-1945. From a reconstruction of the original appearance of the coenurus, which had been cut up after removal into 3 fragments, it is described as follows — a distinctly trilobed vesicle containing 31 scolices, the largest lobe of about 1 cm long, containing 26 scolices in groups of 20, 4 and 2, the next, also about 1 cm long, containing 5 scolices, in groups of 3 and 2, and the smallest lobe, 6 mm long, being devoid of scolices. The cyst wall is very delicate and transparent and shows no signs of proliferation. From the morphology of the scolices and the hooks, it is concluded that the coenurus is immature but all the evidence points to its identification as *Coenurus cerebralis*.

The author reviews briefly the previous records and geographical distribution of coenurosis in man, in which 3 species have been implicated, namely, *C. cerebralis*, *C. serialis* and *C. glomeratus*. He comments upon the difficulty of identifying these species and discusses the validity of the different criteria,

morphological and otherwise which have been employed by various authors separating the species. The possibility is stressed that the coenuri of *m.* may be all one and the same species namely *C. cerebral* that *C. tenuis* may be merely a variety or physiological "strain" and that *C. glomeratus* may represent an immature form of *C. cerebralis*. [See also this Bulletin 1947 v 39 631]

OSIDMAN J J. Parasitismo humano por *Dipylidium caninum* (Linneo 1758) [A Human Infestation with *Dipylidium caninum*.] Arch. Uruguaya Med. Ciruj. y Especialidades, 1946 Aug v 29 No. 2, 171-6.

The English summary appended to the paper is as follows —

History is reported of an infant 8 months old parasitised by *Dipylidium caninum* (Linneo 1758) apparently without symptoms. The worm is evacuated by means of oral administration of both garlic and castor-oil. Considering the form of observation the share of each remedy in the success of the treatment cannot be determined.

BERGERET C. Quelques réflexions sur l'anquilostomiase. [Some Observations on Ankylostomiasis.] Bull. Méd. de l'Afrique Occidentale Française 1947 v 4 No. 2, 159-66.

The author considers that the ancylostome occupies a position of its own among the intestinal helminths on account of the organic disorders which it produces directly by the toxic secretions and indirectly by the grave anaemia which is associated with it.

He draws attention to —

- 1 The gross cardiac anaemia which causes dilatation associated with valvular bruits and true asystoles [véritables arythmies]. Histologically there is parenchymatous myocarditis with hyperplasia and fatty degeneration of the fibres and diffuse interstitial infiltration by lymphocytes, polymorphonuclears and fibrocytes.
- 2 The hepatic lesions—centrilobular and midzonal atrophic or fatty degeneration contrasting with dilatation and congestion of the sinusoids in the periportal region and hypertrophy of the Kupfer's cells with melanin-pigment—which are characteristically those associated with anaemia.
- 3 The importance of the haemoglobin factor and the fact that even without dislodging the parasite—often a difficult task—it is possible to ameliorate the anaemia to a great extent by large doses of iron. L. E. 3 after

FLOCH, H. & CAM IN R. Sur un nouveau cas de pseudo-mylome rampante à localisation en Guyane française. [A New Case of Creeping Erythema caused by *Ancylostoma brasiliense* in French Guiana.] J. Méd. Faculté de la Guyane et Territoire de l'Inini. Publication N° 165 1948 F b 4 pp. 3 figs.

CROFTON H. D. The Ecology of Immature Phases of Trichostrongyle Nematodes. I. The Vertical Distribution of Infective Larvae of *Trichostrongylus reticulatus* in relation to their Habitat. Parasitology 1945 [1946] v 39 No. 1/2, 17-25 8 figs. [14 refs.]

CROFTON H. D. The Ecology of Immature Phases of Trichostrongyle Nematodes. II The Effect of Climatic Factors on the Availability of the Infective Larvae of *Trichostrongylus reticulatus* to the Host. Parasitology 1946 [1947] v 39 No. 1/2, 25-36 8 figs. [21 refs.]

HOAT, O D Iets over de overbrengers van de *microfilaria malayi* in het geneeskundig ressort Boven Mahakam [*Vectors of Microfilaria malayi in Upper Mahakam*] *Geneesk Tijdschr v Nederl-Indië* 1942, Feb 17, v 82, No 7, 302-6, 4 figs on 1 pl

The English summary appended to the paper is as follows —

"*Mansonia longipalpis*, *Mansonia annulatus* and *Mansonia indiana* already known as vectors for *filaria malayi* in other parts of the Netherlands-East-Indies were proved to be responsible for the presence of filariasis *malayi* in the Upper Mahakam district of Borneo. A new carrier could be added *Coquillettidia crassipes*, in which under experimental conditions a 26 per cent proboscis infection could be obtained. Larvae of *Mansonia*s and *Coquillettidia*'s can be found attached to the roots of *Eichhornia crassipes*, but also of other kinds of swamp-plants with fluttering roots *Ipomoea reptans* Poir (kangkong), *Hygrophyla spec*, *Sparganophorus vaillantii* Crantz."

GALLIARD, H & NGU, D V Recherches sur la filariose. Choix d'une technique de numération des microfilaries du sang [*Choice of Technique for enumerating Microfilariae in the Blood*] *Ann Parasit Humaine et Comparée* 1947, v 22, Nos 3/4, 158-63

In endeavouring to discover the optimum procedure for estimating the number of microfilariae in blood, the authors established the following points —

- 1 It is immaterial whether the blood be taken from the finger or the ear
- 2 Peripheral blood is slightly richer in microfilariae than is blood taken from a vein
- 3 Microfilarial counts in a large volume of blood are no more accurate than in a small quantity
- 4 Microfilarial counts of haemolysed blood in a moist chamber gave better results than with thick stained films

HARTZ, P H & VAN DER SAR, A Tropical Eosinophilia in Filariasis. Occurrence of Radiating Processes about Microfilariae. *Amer J Clin Path* 1948, Aug, v 18, No 8, 637-44, 4 figs [19 refs]

Enlarged lymph glands were removed from the anterior axillary fold of a woman, a native of Curacao. On gross section they were greyish red and showed numerous small yellow spots. On microscopic section, the general architecture of the gland was seen to be preserved. The lymphocytes in the lymphoid tissue were almost completely replaced by plasma cells between which were eosinophils in varying numbers. The yellow spots were areas of infiltration by eosinophils. These were seen in both cortex and medulla. The cells in the centre of these infiltrates were sometimes degenerated, but retained their eosinophilic character. The only other cells present were histiocytes with pale vesicular nuclei. Large numbers of eosinophils were present in the local blood vessels.

In many of the eosinophil infiltrates typical microfilariae were found. Many of these were surrounded by a homogeneous acidophilic membrane from which pseudopodic processes of various shapes and thicknesses radiated, these were also acidophilic and "sometimes fairly refractile". Neither the membrane nor the processes stained with Weigert's fibrin stain.

A leucocyte count showed a total of 20,100 per cmm with 23 per cent eosinophils, 66 per cent neutrophils, 4 per cent lymphocytes and 7 per cent monocytes. No microfilariae were found in the blood. A diagnosis of tropical eosinophilia was made. The patient was given two injections of mapharsen.

Five months later the leucocyte count was 11,300 with 4 per cent. eosinophils. She had no subjective symptoms and roentgenograms of the chest showed no abnormality.

The authors had observed these radiate formations and local eosinophilic infiltrations in other instances of nematode infection for example in a case of filarial epididymo-orchitis and in strongyloidiasis. In both instances the worms were necrosing in the tissues. They consider that it is a non-specific allergic phenomenon in a sensitized person.

OLIVIER G. Etude critique des données nouvelles sur l'éléphantiasis.
[Critical Study of New Data concerning Elephantiasis.] *Méd. Trop.*
Marseille. 1947 Nov-Dec. v 7 No. 5 439-64 9 figs. [64 refs.]

The author discussed the mechanism of the production of elephantiasis using data of his own and of his colleagues.

An analysis of the oedema fluid and blood serum in elephantiasis showed that the protein content of the former was rather lower than one would expect in an inflammatory exudate and that in both the calcium was high. Further studies showed that it was mainly in the oedematous cases of elephantiasis that the serum calcium was high (mean 10.73 mgm. per cent.)

Whereas the serum calcium was normal in the sclerodermatous cases, analysis of the calcium content of the sclerodermatous skin showed that the average calcium content was increased by 83 per cent. These observations suggest that the fibrosis in the skin is due to impregnation with calcium.

The author points out that in the early stages when there is inflammatory oedema and sometimes osteoporosis the blood calcium is high whereas later when scleroderma has developed there is often subjacent ossification and the serum calcium has returned to normal. He therefore believes that disturbance in calcium metabolism is a secondary phenomenon.

Lymphography of elephantoid limbs has confirmed the fact that there is dilatation and stasis in the lymph vessels of the limb but has given no indication if this stasis is mechanical or functional, or whether the cause is regional or general further it has not actually been demonstrated that the obstruction is in the glands though it is generally assumed that it is there. Phlebographic studies have shown that there is some associated venous congestion.

Sympathectomy produces a marked reduction in the size of the limb. This indicates that there is a functional element (spasm) as well as obstruction in elephantiasis. Parathyroidectomy causes a fall in blood calcium and has a transitory effect on the limb in one case it caused a reduction in the size of the limb but the tissues became hard and resistant.

In conclusion the author considers that the mechanism of the production of oedema has still to be demonstrated before any effective treatment can be devised.

L. E. Nafis

THETFORD N D OTTO, G F BROWN H W & MAREN T H. The Use of a Phenyl Arsenoxide in the Treatment of *Wuchereria bancrofti* Infection.
Amer J Trop Med 1948 Jul 28 v 4 577-83 13 ref 1

The substituted phenyl arsenoxides, a new group have markedly lethal action against the microfilariae of *Dirofilaria immitis* and *Leishmania canis* *in vitro* and several of them kill the adult filariae when given in well tolerated doses to their hosts. Arsenamide (i.e. *p*-(bis-(carboxymethyl-mercapto) aryl)-benzamide) kills all the adult worms of *D. immitis* when given intravenously in daily doses of 0.23 mgm. A per kilogramme for two weeks but does not produce an immediate reduction in the microfilaria count.

Seven patients with *W. bancrofti* infection were treated with this drug. It was given intravenously as a sodium salt in a 2 per cent solution in buffered phosphate (pH 7.0) in daily doses of 0.05 ml per kilogramme body-weight (=10 mgm of arsenamide or 0.2 mgm of As) for 15 days. Microfilaria counts were made before, during, and after treatment, the last counts being taken from 12 to 17 months after treatment. In six cases the pre-treatment counts were respectively, 307, 4, 726, 19, 150 and 143 microfilariae in 0.1 ml of night blood. In each case, the microfilariae were practically eliminated by the end of treatment. In 3 cases very small numbers (1 to 3) were found during the follow-up, in one of these as late as the 17th month, but in all except this one the final count showed none. The treatment caused signs of slight toxicity in three cases, and febrile or local reactions in 4 others, the latter were probably due to the death of the adult worms.

In the 7th case no microfilariae were found at any time but the patient had overt signs of filariasis, and gave a positive skin test with *dirofilaria* antigen. After treatment there was a temporary improvement in the scrotal oedema, and the eosinophil percentage which had risen from 4 to 16 during treatment fell to nil in 100 white cells.

Two patients were treated with mapharsen (oxyphenarsine hydrochloride), one, an adult male negro aged 28, was given 0.06 gm doses daily for 10 days.

The microfilaria count fell from 360 in 0.1 ml during the day and 14 during the night (he was a night worker) to nil two and three weeks after treatment. The other, a 23-year-old Porto Rican, was given 1.0 gm by the constant drip method over a period of 5 days. His count fell from 4 to 5 microfilariae "per drop of freshly drawn night blood" to nil immediately after treatment and again in 3 and 28 months. In this second case, however, an adult filaria was removed by biopsy at the time the treatment was given.

The authors point out that the past failures with arsenical drugs have been associated with smaller dosages.

L. E. Napier

KERSHAW, W. E. & BERTRAM, D. S. Course of Untreated Infections of *Leishmanosoides carinii* in the Cotton Rat [Correspondence] *Nature* 1948, July 24, 149-50.

The authors urge that caution be used in interpreting the results of chemotherapeutical studies in filariasis, in which the experimental animals employed are cotton rats which have acquired their filarial infections naturally in the field. Their experience with cotton rats experimentally infected in the laboratory and observed for a year or more, shows that the duration and intensity of the microfilariae in the blood varies considerably in different rats, and hence that conclusions from treated infections should not be drawn without due regard to findings in untreated controls.

The general course of the blood infection in rats exposed to infection on one occasion was as follows: microfilariae appear in the blood after 51 days and increase in numbers during the next month or so, after which the number tends to remain more or less constant with wide variations about the mean. But in one rat the intensity was maintained at 140 to 240 microfilariae per cmm for 12 months, while in another the intensity was maintained at 80 to 190 microfilariae per cmm for six months, but dropped progressively during the following 3 or 4 months and finally disappeared. In another series of rats which were infected by mass exposure on several occasions, some showed counts of 1,500, 840, 675, 450 and 140 microfilariae per cmm about the third or fourth month later and after the seventh or eighth months these counts dropped to 530, 45, 30, 10 and 20 respectively, while in other rats which died seven to twelve months after their last exposure, many of the adult worms were dead and encapsulated.

Another important variable is the relationship between the death of the adult worm and the disappearance of the microfilariae from the peripheral blood. The persistence of microfilariae in the peripheral blood in the absence of the adult is known to vary from days to weeks and even months.

VARGAS L. Notas sobre la oncocerciasis. VI Consideraciones sobre la biología de las larvas de simúlidos. [Notes on Oncocerciasis. VI On the Biology of Simuliid Larvae.] *Gac. Méd. de México* 1947 Dec. 31 v. 7 No. 6 346-52.

Simulium larvae feed on particles brought down in running water—bacteria, fragments of phanerogam plants, various algae such as *Ulothrix*, *Cladophora*, *Vantheria*, *Coccoloba*, *Euglena*, *Spirogyra*, and diatomaceous copepods, etc. The larvae live preferably in fairly rapid flowing water but not too rapid. The author shows how these factors—the presence of the appropriate food, the character and flow of water, the temperature, protection from winds, etc.—participate to facilitate the adults in the deposition of their ova and the larvae in developing in the different areas of Chiapas, Mexico, in parts of which *Oncocerca* is rife.

PICCOLI Annibale. Contributo alla terapia della oncosiaria nell'infanzia col violetto di genziana. Osservazioni relative a casi trattati in ambiente tropicale. [The Treatment of Enterobiasis in Infants by Gentian Violet.] *Acta Med. Italica* 1948 July, v. 3 Suppl. No. 3 11-20 (37 refs.) English summary.

Much of this article is taken up with records of the prevalence of helminthiasis in different countries. The author then goes on to give an account of the treatment of three groups of patients: (1) Twenty-six prisoners of war 23-45 years of age in Kenya [the title of the paper restricting the observation to infants is not quite correct]; (2) Sixty-four Somali children; (3) Thirty-two "national" [Italian] children. To those of the first group were given gentian violet [preparation not stated] 6 cgm. twice a day during two periods of 8 days, with a week's rest between. The drug was well tolerated, pruritus and soon disappeared and in 25 the ova were no more seen. In the case of the other the ova reappeared after an absence of 30 days. In the second group there were 35 boys and 29 girls, their ages ranging between 7 and 12 years. The symptoms exhibited were marked anorexia, vague abdominal pain, intense nocturnal pruritus and intermittent diarrhoea with much mucus and sometimes with blood. In addition to *Enterobius* *D. phyllo-bulbaceus* ova were common and also *Ceratomyxa* and *Blasphysis*. The mode of administration was 1 cgm. for each year of age, divided into 3 keratin-coated capsules, one after each of the principal meals—three courses of 5 days treatment with interval of 5 days free. Ova were passed in large numbers at first but symptoms cleared up and

at the end of treatment no ova could be found in 61, a month later re-examination showed that 60 were still negative, 4 positive. The age of those of the third group were between 3 and 8 years. In six of the children the disease had persisted for about 2 years. The gentian violet was given in two courses of 5 days, with an interval of the same length and dosage as for group 2, 1 cgm, for each year of age. With both groups calomel ointment was applied locally for the pruritus. During the first 5-day course many worms were passed, after which they disappeared. Faecal examination 20-40 days after cessation of treatment showed 29 cured, three others aged 3, 4 and 7 years, were negative at 20 days but positive again at 40 days. These were subjected to another course of two 5-day treatments and they became negative and were still negative when re-examined after 2 months. Three mothers, aged 25, 28 and 32 years, who were positive, were also successfully treated by this method.

ROSS, Winifred M. A Note on the Collection of Live Adults of *Trichinella spiralis* *Canadian J Comp Med* 1948, June, v 12, No 6, 152-4, 2 figs

While the separation and collection of encysted larvae of *Trichinella* can easily be accomplished, the collection of living adults in numbers sufficient for the preparation of an experimental test antigen proved a difficult problem which was solved as follows: a rat is killed 5 days after oral administration of infective larvae, having received only water for 24 hours prior to killing. The gut is removed from the level of the duodenum to the caecum and is opened and rinsed in a beaker of warm saline. In a shallow pan of warm saline, the mucosa is stripped off with a glass slide and the muscular part of the gut is discarded after rinsing. The suspension of worms and mucosa in saline is then pipetted on filter paper, through which excess saline passes. The filter paper is then placed face down in a Petri dish of warm saline and the adult worms, stimulated by the heat, detach themselves from the paper and the mucosal shreds and fall to the bottom of the dish. They can be further separated from remaining debris by repeating the process. It is important that the saline be kept warm during the procedure and this is best effected by placing the Petri dish in a sink of gently flowing hot water, producing temperatures of up to 42°C. The technique is illustrated by two line drawings. J J C Buckley

DEFICIENCY DISEASES

CRAWFORD, J N & REID, J A G. Nutritional Disease affecting Canadian Troops held Prisoner of War by the Japanese *Canadian J Res Sect E Med Sci* 1947, Apr, v 25, No 2, 53-85, 2 figs

In Hong Kong, as in other prisoner-of-war camps in the Far East, the effects of malnutrition developed against a background of intercurrent infection and (1401)

excessive physical work. The diet is described in general terms throughout the period of imprisonment it was deficient in calories, fat, animal protein, and vitamins, being worst at the beginning in 1942. The authors have not attempted to estimate the intake of individual nutrients, nor to correlate intake levels with the appearance of the various deficiency states.

The greater part of the report is devoted to a detailed and objective description of the nature, course, and response to treatment of the symptoms and signs of deficiency. Preconceived ideas about aetiology and the rôle of specific vitamins have been scrupulously avoided. The value of the work is further increased by the fact that in some cases it was possible to make follow-up observations after repatriation of the troops to Canada.

The first symptoms to develop were urinary urgency, inefficiency of the sphincter, polyuria, and nycturia (nocturnal polyuria). These first appeared after only a week of imprisonment and continued until 1945. Nearly 100 per cent. of the men were affected. The average urine volume was 8-8 litres in 24 hours. Nycturia was relieved whenever there was an increased intake of meat. The symptoms were worse in cases with gross neurological disturbance.

Next oedema appeared. [The time sequence is to be noted. SUGLAND has described nycturia accompanying famine oedema in Holland and Germany (see *Bulletin of Hygiene* 1949, 1, 24 Jan.) but says nothing about which came first.] Nearly 80 per cent. of the camp population were affected. At first oedema responded well to rest in bed, and dramatically to intramuscular injections of thiamin. After 1942, however, many cases were resistant to thiamin. It is suggested that these may have been caused by protein deficiency.

Cardiac changes such as tachycardia, arrhythmia, and systolic murmurs were common but there was little clinical evidence of cardiac enlargement. In patients with infections cardiac collapse was the common cause of death, and it was estimated that the cardiac age was advanced 20 years. Acute cardiac failure does not seem to have been found in the absence of infection. All the cardiac signs responded to treatment with thiamin.

Neurological changes developed at an early stage. These included paraesthesiae, glove-and-stocking hypoesthesia, calf tenderness, and changes in the deep reflexes. Loss of visual acuity was common, accompanied by contraction of the visual fields and scotomata. When ophthalmoscopic examination became possible optic atrophy was found in some cases. An interesting observation is that although there were no complaints of deafness during the period of imprisonment, audiometric tests made after repatriation showed a diminished perception of high frequency tones.

A serious cause of disability was the condition known as "electric feet." This conformed to the descriptions of painful feet in other P.O.W. camps. There was some evidence of vascular disturbance: the pain was worse at night and was relieved by immersing the feet in water. Gangrene sometimes occurred. There was no response to vitamin B₁, but nicotinic acid in doses of 70 mgm. each day intramuscularly reversed the progress of the syndrome. There has been conflict of opinion and evidence about the efficacy of nicotinic acid in this condition: the authors emphasize that in their cases, because of a probable impairment of absorption, the vitamin was given parenterally. It was noted that subjects of European stock who had been born in Hong Kong and lived all their lives there were much less liable to "painful feet" than the troops from Britain or Canada.

As in other P.O.W. camps scrotal dermatitis and lesions of mucosae were common. Conjunctivitis was sometimes accompanied by corneal ulceration, which responded to treatment with shark-oil. In the autumn of 1942 there was an epidemic of pellagra dermatitis, which cleared up with nicotinic acid.

Swelling of the breast was found in a moderate number of cases. This first appeared in 1942, later became less frequent, and recurred after release and return to European food.

In conclusion, the authors discuss the question of psychological changes. They found no evidence of any specific emotional disturbance, if anything, there was euphoria rather than depression.

LANDOR, J V. The Effect of Nutritional Disorders on the Skin and Mucous Membranes as observed in the Civilian Internment Camp, Singapore, during the Japanese Occupation of Malaya. *Brit J Dermat & Syph* 1948, Jan, v 60, No 1, 1-9, 1 fig [13 refs]

Skin affections were very common among internees in the civilian camp in Singapore, especially during the latter two years of the Japanese occupation. Among them were some which appeared to be of nutritional origin.

Nicotinic acid deficiency—Pellagrous dermatitis conformed to classical descriptions. Diarrhoea and mental disorders were not commonly associated [The condition of the tongue is not mentioned]. The condition responded rapidly to nicotinic acid and the mass curative and preventive effect of under-milled rice was very evident.

Riboflavin deficiency—Stomatitis and eczema of the scrotum (oro-genital syndrome) were seen in a number of cases. The condition responded to riboflavin internally when this was available.

Blood blister disease—A large number of patients were seen whose complaints were of multiple superficial blood blisters mainly occurring on the palate or buccal mucosa. These blisters were irregularly associated with other deficiency diseases and no available treatment was found to be effective. The author draws a parallel between this condition and that known in Africa as "onyalai". [There are, however, many points of difference between the two, particularly the severe constitutional disturbance and grave prognosis in onyalai, whereas the blood blister disease in the camps was "in general not a troublesome condition".]

Subcuticular haemorrhages—Petechial or larger haemorrhagic spots appeared in or under the skin particularly on the backs of the hands, legs and thighs. No available treatment proved of value.

Erythema nodosum—36 cases of a disease resembling erythema nodosum were seen during the last year of internment. The association with other nutritional disorders was slight, but it seemed probable that malnutrition was part of the cause.

Sword bean dermatitis—In a few subjects, severe pruritus and eczematous type of dermatitis followed the ingestion of sword bean (*Canavalia ensiformis*).

Dean A Smith

RAMAN, T K. Pellagra in India. *Indian Physician* 1948, June, v 7, No 6, 141-72, 22 figs on 4 pls [Numerous refs]

The term "pellagra" is used to describe a variety of conditions. In presenting a clinical study of 102 cases, the author uses the term in its strictest sense: symmetrical exfoliative dermatitis with a sharply demarcated margin was the diagnostic criterion. The cases occurred in Vizagapatam where rice is the dietary staple. The introduction of maize as a common item of diet in 1945 has not been followed by any increased incidence.

It usually occurred on the exposed areas of skin, but it was occasionally found also in unusual situations such as the groins and under the breasts.

Gastro-intestinal symptoms were common and included anorexia and diarrhoea. Gastric analysis showed either greatly diminished acidity or achlorhydria. X-ray examination showed gastric atony. Glucosuria, sometimes present, was not a marked feature. Evidence of associated B complex deficiencies such as angular stomatitis were common and beriberi and hypoproteinaemic oedema co-existed in many cases.

The cerebrospinal fluid was examined in twelve cases and no abnormality was found. Nor was any change attributable to pellagra, detected in the cardiovascular system. Sedimentation rate was normal in cases uncomplicated by other diseases. Fat analysis of the stools indicated defect in both digestion and absorption.

Treatment by means of a full diet, crude liver extract and nicotinic acid produced rapid improvement in the majority of cases. The paper is illustrated with some good photographs of pellagrous skin lesions.

(In the discussion of the aetiology of pellagra almost all important recent work is quoted but the exposition is less lucid than that of the clinical study and does not greatly clarify a complex subject.)

DAVID A. SMITH

DE PAIVA, B. H. C. Modificações electrocardiográficas na pelagra. [Electrocardiographic Changes in Pellagra.] *Rev. Brasileira Med.* Rio de Janeiro, 1948, Aug. v. 5, No. 8, 586-8, 2 figs. [10 refs.]

The English summary appended to the paper is as follows —

"The author reports the details of a case of pellagra with electrocardiographic abnormalities with return to normal conditions, after exclusive administration of nicotinic acid. Several authors such as Ashman and Hull, deny the existence of those anomalies stating that those found in similar cases are due to deficiency of thiamine and not of nicotinic acid (even in the case of pellagra). However, care was taken to administer only the latter in doses of 400 mg. p. d. during 10 days—a total of 4 grams.—and a completely normal record was obtained. The principal anomaly was the reversion of T in C13. There are several cases under observation the results of which will be made known in later publication.

CORRILL, V. L., CREDITOR, H. & STEWART, G. E. S. Millet Beer and Peanuts as Protective Foods in Africans. *J. Trop. Med. & Hyg.* 1948, July, v. 51, No. 7, 140-44, 1 graph.

An outbreak of dysentery and deficiency disease occurred among African prisoners of war in the Anglo-Egyptian Sudan who were subsisting on a diet low in calories with millet as the staple. The clinical picture was dominated by the signs and symptoms of pellagra although the ration contained no meat. There were also some cases of scurvy, beriberi and burning feet.

The camp population consisted of two groups, Christians and Moslems. Cases at first occurred only among Christians who had been eating no meat, whereas the Moslems had been receiving 8 oz. a week. After the beginning of the outbreak, a new diet scale was introduced, the meat ration was increased, and millet-beer and peanuts were added to the ration as sources of vitamins. The Moslems refused the beer and thus became a control group for the effects of beer.

In both Christians and Moslems the additions to the diet were followed by an increase in deficiency disease. In the Christians the increase was only temporary whereas in the Moslems it persisted. Thus it is claimed demonstrates the value of millet-beer as a protective food, since the rations were in

respects equal To explain the rise in morbidity, the authors postulate a stimulation of metabolism resulting from an increased caloric intake They suggest that whenever the caloric value of a deficient diet is increased, protective concentrates should be given at the same time, as otherwise marginal deficiency states may be made worse

The lower morbidity in the Christian beer-drinkers is in agreement with earlier observations of one of the authors He found that among the Sudanese the "burning feet" syndrome affected mainly those who did not drink millet beer, and that it did not occur in tribes eating peanuts

[The suggestion that vitamin concentrates should be given when the caloric value of an inadequate diet is increased, if taken in a general sense, is likely to prove discouraging to workers in the field, since these concentrates are often difficult to obtain The commonly accepted view is that, except in the case of those who are actually ill, the aim should be to supplement the diet with natural foods, such as the millet-beer and peanuts used by Dr Corkill and his colleagues Their observations, and the hypothesis put forward to explain them, suggest that such measures are not enough In field work there are many uncontrollable variables, in the reviewer's opinion, the data do not form an adequate basis for a recommendation of such significance From the theoretical point of view, there is no clear-cut evidence that the requirement for any vitamin except thiamin is affected by an increased caloric intake]

J C Waterlow

CORKILL, N L, CREDITOR, H & STEWART, G E S **Millet Beer and Peanuts as Remedial Foods in Polyhypovitaminosis** *J Trop Med & Hyg* 1948, Aug, v 51, No 8, 160-68

The authors have previously described how they used peanuts and beer made from sprouted millet as prophylactic nutritional supplements in a prisoner-of-war camp in the Anglo-Egyptian Sudan [see above] They now describe the effect of giving the same foodstuffs to patients actually suffering from manifestations of deficiency

From a camp population in which there was a considerable incidence of multiple B complex deficiency and of scurvy, 100 men were chosen and divided into five groups Food supplements of beer, peanuts, peanuts and beer, and marmite (of questionable age) were made available to the first four groups respectively while the fifth remained as a control

The progress of each group was recorded by means of scoring the severity of ten physical signs believed to be stigmata of malnutrition On this basis and on that of hospital admissions and deaths, it is clear that the group on both nuts and beer fared best and the controls worst with the groups on nuts alone and on beer alone approximately equal and intermediate

[The difficulties of life and the practice of medicine in a prison camp make the collection of precise data almost impossible The statistical value of the present results is somewhat diminished by three circumstances (1) the questionable validity of the sampling, (2) the provision, simultaneously with the supplements, of a greatly improved basic diet, including 6 oz each of meat and fresh vegetables daily, and (3) the fact that though the supplements were provided the subjects did not always eat all, or even any, of them None the less the results suggest strongly that peanuts and millet beer were valuable supplements to a diet which up to the time of the experiment had consisted predominantly of sorghum, and hastened improvement even when considerable quantities of meat and vegetables were added]

ROYCE, K. Infantile Hepatic Cirrhosis in Jamaica. *Caribbean Med J* 1944
v 10 No. 1/2, 16-48 [5 refs.]

Nearly 300 cases of cirrhosis of the liver in infants and children were seen each year at the Kingston Public Hospital, Jamaica, between 1936 and 1941. This figure indicates the magnitude of the problem, since the population of the whole island is only 1½ millions.

This paper is based on 32 cases. The author's objective has been to do an analysis of case-histories and an enquiry into the patient's social and economic background, to throw some light on the aetiology of the disease. Cirrhosis is found only in the children of the poorer classes. It is commoner in boys than girls. There is no evidence of a hereditary or familial factor. Two points stand out from the case-histories: (i) the patient showed a higher incidence of infections of the chest, gastro-intestinal tract and skin than the normal child population; (ii) the diet estimated qualitatively was in all cases inadequate in protein, vitamins and minerals and adequate only in caloric content.

The age at the time of admission to hospital ranged from 1 month to 8 years. No child was seen before weaning, which took place at an average age of 8 months. After weaning the diet consisted mainly of starch, roots and porridge with small supplements of milk, salt fish, and vegetables. The average age of onset of symptoms was 4 years. The common presenting symptoms were abdominal distension, anorexia, fever and vomiting. On examination ascites was present in all but one case and nearly all had pyrexia and hepatomegaly. Oedema of the legs was present in 6, jaundice in 5 and splenomegaly in only 3. Most of the children were underweight for their age but specific signs of vitamin deficiency were uncommon. The Kahn test was negative and no significant changes were found in urine or stool. The blood showed a moderate anaemia in the majority of cases, a reduction of the albumin:globulin ratio, an increased sedimentation rate and sometimes a mild leucobasophilia. Histological examination of the liver in one fatal case showed strands of fibrous tissue radiating from the portal channel surrounding lobules and cutting across them. Swollen and necrotic parenchymal cells were seen at the periphery of some lobules.

The author was able to follow the course of the disease over a period of 3 years in all but 3 of the 32 cases. Nine recovered and were free from symptoms, 9 showed some recovery but symptoms persisted, 7 died from intercurrent disease and 4 died of progressive hepatic failure within 6 weeks of the onset. All those in hospital received a good mixed diet, some in addition were given liver extract with yeast or iron. Although no precise comparison is claimed, it was felt that liver had a distinctly beneficial effect. Another factor affecting the prognosis was the occurrence of intercurrent infection. This was usually followed by a return of ascites, nausea, and vomiting.

In discussing aetiology the author believes that dietary deficiency alone is not enough to account for this type of cirrhosis, since only a small proportion of children of the same economic status eating similar food, are affected. He suggests that infection, particularly repeated infection, may be the precipitating factor, since it has been shown experimentally that malnutrition increases the susceptibility of the liver to many different kinds of poisons.

[This is the first paper dealing with cirrhosis in the tropics of which the reviewer is aware in which the cases have been followed systematically over a period of years. Dr. Royce does not claim that the data presented give a complete picture of prognosis and incidence. It is possible that many sub-clinical cases occur in which hepatic fibrosis reaches an apparent stationary state as is suggested from the post-mortem studies of DAVIS in East Africa (this Bulletin 1948 v 45 #33). There must presumably be a tendency to

compensation or partial recovery, since, as the present author points out, clinical cirrhosis in adults is not particularly common in Jamaica. One criticism may be raised—it is perhaps unsound to assume the identity of cirrhosis in Jamaica with infantile, so-called biliary, cirrhosis in India, since there are important clinical differences. In the latter, the onset usually occurs at 1–2 years, and the course is more rapid and more uniformly fatal. Splenomegaly and jaundice are present at an early stage.] *J C Waterlow*

SPRUE

CHRISTOFFERSEN N R & HEINTZELMANN F Folinsyreterapi ved leverrefraktaer makrocytaer Sprueanæmi [Macrocytic Anaemia in Sprue, refractory to Liver Treatment, cured with Folic Acid] *Nordisk Med* 1948, Oct 1, v 40 No 40 1779–80 1 fig English summary (6 lines)

Report of a case

FERGUSON, J W & CALDER, E Folic Acid in Non-Tropical Sprue with particular reference to Fat Absorption and Radiological Appearances of the Small Intestines *Glasgow Med J* 1948, Oct, v 29, No 10, 341–56, 13 figs [18 refs]

“The results are reported of an investigation into the effect of folic acid on seven cases of non-tropical sprue

“Of the cases in which the bone marrow was normoblastic, one patient appeared to obtain subjective improvement. In the others, the general condition was unaltered or had deteriorated. There was no evidence of improvement in fat absorption, biochemical findings, blood picture or intestinal pattern in any of the patients

“Of the two patients who were known to have had megaloblastic marrow reaction, one showed clinical and haematological improvement and a return of the intestinal pattern to normal, but the steatorrhoea persisted. In the other there was no apparent clinical or haematological improvement but again there was a striking radiological improvement without improvement in fat absorption”

HAEMATOLOGY

VAN DER MERWE, C F The Blood Picture of Healthy Europeans in South Africa *South African Med J* 1948, Aug 14, v 22, No 15, 482–7, 7 graphs [49 refs]

Blood counts were carried out on 700 healthy Europeans (374 males and 326 females) living in South Africa at heights between 3,000 and 5,500 feet above sea level

The author's figures have been arranged in tabular form

		Approximate range	Extremes
Red cells—10 ⁶ per cmm	Males	5.0 to 6.9	4.0 & 7.8
	Females	4.5 to 6.5	4.0 & 7
Haemoglobin gm. per 100 ml.	Males	16.0 to 1.6	14.4 & 23.2
	Females	15.2 to 20.0	14.4 & 21.6
Mean diam. ters of red cells, μ	Males		7.1 & 7.8
	Females		7.1 & 8.1
Leucocytes per cmm.		4,500 to 11,000	3,500 & 18,000
Eosinophils per 100 leucocytes		1 to 8	0 & 28
Monocytes per 100 leucocytes		0 to 1	— & 20
Lymphocytes per 100 leucocytes		23 to 53	16 & 63
Rod-shaped leucocytes per 100 leucocytes		2 to 20	0 & 28
Polymorphonuclears per 100 leucocytes		30 to 60	23 & 70

For estimating the mean diameters of the red cells he used Fijfer's blood cell tester and for the differential count he counted only 100 leucocytes.

The author concludes that "there exists a much wider range in normal people than is usually assumed. Many supposedly abnormal blood pictures are included in this range. Blood pictures when possible should be compared not with traditional standards but with other blood pictures of the same person."

[The results are shown in a series of carefully-drawn (and well-reproduced) curves and to get the full value of this paper one must refer to these. This is made necessary by the author's failure to apply statistical methods to the figures which he has so laboriously compiled. He has apparently selected entirely arbitrarily what we have interpreted as the range (he has occasionally used the word) for example he writes "Curve I shows that values of approximately 5.0-6.9 million red corpuscles per cmm. were found in 374 healthy males— and "Extreme values of 4.0-7.8 millions for men" were occasionally found." The extreme arbitrariness of his choice of "range" is shown by the fact that from his erythrocyte curve it is apparent that only some half dozen instances at each end of the curve are excluded from his range (5.0 to 6.9 million) whereas he states that 1,137 persons no eosinophils were found (range 1 to 8 per cent.) The application of elementary statistical methods would have increased the value of this paper considerably. From his figures for polymorphonuclears in the text (quoted above) he has apparently excluded "rod-shaped leucocytes" but in curve VII the polymorph (sic) curve extend from 30 to 80 per cent and obviously includes all neutrophil granulocytes.)

DAVIDSON, L S P **Pteroylglutamic Acid (Folic Acid) Therapeutic Indications and Limitations** *Edinburgh Med J* 1948, July, v 55, No 7, 400-411 [32 refs]

Synthetic folic acid contains the amino acid, glutamic acid, linked with para-aminobenzoic acid and the pteridine nucleus. The name pteroylglutamic acid (PGA) is preferable. In natural foods and tissues it occurs mainly in the form of conjugates, the most important of which is pteroylhaptaglutamic acid or PHGA. These conjugates have been shown by biological assay to be inactive, but, if the additional molecules are removed by hydrolysis, the property of stimulating the test-organisms is regained.

This is of interest because it suggests that the fundamental defect in Addisonian pernicious anaemia is the inability of the patient to utilize PHGA by its conversion to the free form, this can be done *in vitro* by the use of enzymes such as takadiastase and by the action of acids and alkalis, while in the living animal hydrolysis is probably accomplished by the action of a naturally occurring enzyme called Vitamin B₁₂ conjugase found in many organs, such as the liver, kidney and pancreas. Some organs indeed contain also inhibitors of the conjugase system. Biological assay of PGA in foods becomes complicated, so that published reports of the content of PGA vary widely. It is more easily damaged by cooking than other members of the vitamin B₁₂ complex and the process of canning has a deleterious effect. The daily intake by a normal person is less than 1 mgm, though it is possible that this amount may be augmented by the production of PGA by bacterial synthesis in the intestinal tract. This certainly occurs in the rat which can manufacture up to 70 per cent of its daily requirement by this method, so that sulphonamides must be administered in order to produce the PGA deficiency syndrome, but proof that this synthesis occurs in man is not available.

Certain synthetic compounds, such as *d*(-)-methyl folic acid, have an antagonistic action to PGA. This action can be shown by their effect in inhibiting the growth-promoting action on *Lactobacillus casei*, or *Streptococcus faecalis* β . Deficiency syndromes in animals fed on a PGA-deficient diet develop more rapidly and severely when these antagonistic compounds are added to their diet.

Pteroylaspartic acid, though closely related chemically to PGA, is therapeutically ineffective in Addisonian pernicious anaemia and is even antagonistic to PGA, but not to purified liver extract. Sufficient evidence is not yet available to explain the mechanism by which PGA produces its dramatic effects on the haemopoietic and alimentary system, but there is ample evidence to show that PGA is neither Castle's intrinsic or extrinsic factor nor the interaction product which is stored in the liver and is present in purified extracts given parenterally. In the chemical processes employed for the preparation of liver extracts, those fractions which contain PGA are discarded so that the end products are practically devoid of it, but since the haemopoietic effects produced by the daily administration of 1-2 mgm of PGA are indistinguishable from those resulting from a single injection of refined liver extract containing only a few microgrammes of the active anti-anaemic principle, it appears reasonable to believe that their mechanisms of action are closely related. As a working hypothesis it is suggested that the fundamental defect in Addisonian pernicious anaemia is the patient's inability to utilize PHGA; furthermore, that this metabolic error is directly attributable to the patient's inability to produce the active principle present in purified liver extract consequent upon a failure of gastric secretion of Castle's intrinsic factor. Although the mechanism is still obscure, the fact remains that a deficiency of PGA with its haemopoietic syndrome can result from either defective intake, or defective absorption, of PHGA, or from a defective production of the factor present in purified liver extract.

As a member of the vitamin B complex PGA should function according to certain well defined principles which are applicable to vitamins in general. The clinical features characteristic of any particular vitamin deficiency state should appear consistently when a certain stage of deficiency has been reached, but will disappear when the deficiency has been corrected. The clinical features should not respond to the administration of any other substance but the vitamins concerned.

The manifestations of PGA deficiency are concerned with the haemopoietic and alimentary systems. In general it will be found that all types of anaemia with a normoblastic marrow fail to be influenced favourably by PGA.

The intramuscular injection of large quantities of PGA is wasteful and uneconomical for much of the injected material is rapidly excreted in the urine. It is much more effective to give 5 mgm. daily by mouth for thirty days than one single dose of 150 mgm. by mouth or injection.

The daily dose of PGA required for optimal blood regeneration varies from patient to patient. The lowest effective dose recorded is 1 mgm. The maintenance requirements of PGA have not yet been finally established. The author has had cases which maintained a normal blood level on a daily intake of 1.0 and 2.5 mgm. over a period of 255 or 384 days respectively.

However in view of the dangers of developing neurological disease to which attention has been called, maintenance treatment of pernicious anaemia with PGA can no longer be recommended. It had been found that a dose of 10 mgm. PGA daily by mouth is effective in the treatment of megaloblastic anaemia of pregnancy and in the sprue syndrome with megaloblastic anaemia. Spinal puncture when repeated thirty six to forty-eight hours after the administration of PGA to all types of megaloblastic anaemia shows the same remarkable transformation of the bone marrow towards the normoblastic state as had been found in pernicious anaemia treated with parenteral liver extract. In pernicious anaemia of pregnancy in nutritional (tropical) megaloblastic anaemia, megaloblastic anaemia of infants and some cases of the sprue syndrome when once the blood picture has been restored, no further maintenance therapy is required.

In the sprue syndrome the results of treatment with PGA are especially good in tropical sprue particularly with megaloblastic anaemia. In idiopathic steatorrhoea with megaloblastic anaemia responses have been good in some cases, though other workers have had negative results. No benefit appears to occur in the majority of cases of coeliac disease in children. Subacute combined degeneration of the cord is neither prevented nor cured by PGA. More serious still is the statement that PGA actually increases the liability to involvement of the nervous system and accelerates its progress. It has been suggested that PGA interferes with the capacity of nerve cells to use glutamic acid.

It therefore appears that PGA is potentially a dangerous drug and must not be employed except for limited periods and in exceptional circumstances in pernicious anaemia and probably in some other cases. A warning is issued against the practice of polyvalent therapy of the anaemias with iron and liver extract simultaneously until the correct diagnosis has been established.

M. J. W. BAKER

SMITH, T. D. STOVE, R. E., GARCIA LOPEZ, G., MILAVTS, F., LOPEZ TOCA, R. & ARAMBURU, T. Thymine, Folic Acid, and Vitamin B₁₂ in Nutritional Macrocytic Anaemia, Tropical Sprue and Pernicious Anaemia. *Lancet*. 1945 Oct. 2 519-20, 4 figs.

Within the last three years folic acid, thymine or 5-methyl uracil, and vitamin B₁₂ have been found to produce blood regeneration in certain types of

macrocytic anaemia Much work is now being done to elucidate the structure of vitamin B₁₂

The extreme variation in the individual response makes it desirable to observe the effect of folic acid, thymine and vitamin B₁₂ in the same person in the same degree of relapse, under comparable conditions and on the same diet. Three patients were selected, each was admitted to hospital in relapse three times and on each occasion was given a different drug, while the diet and conditions of study were kept constant.

The first case was one of nutritional anaemia in a white man of 51, the second a Cuban farmer, aged 70, with tropical sprue and the third a white man of 46 with pernicious anaemia.

Each compound produced a blood response and a definite clinical improvement. The fact that three distinct chemical compounds have proved effective in each of three distinct clinical syndromes appears to suggest that a great deal can be learnt of the pathogenesis of these diseases.

It appears that several thousand times the weight of thymine is required to produce a response similar to that produced by folic acid, and that several thousand times the weight of folic acid is required to produce a response similar to that produced by vitamin B₁₂. The findings suggest that this last-named is by far the most potent antianaemic substance known. A single dose was injected in the case of each patient and the dosage was 6 µgm, 23 µgm, and 15 µgm, respectively.
P Manson-Bahr

BIRKS, P. H. A Note on the Value of Folic Acid in the Treatment of Macrocytic Anaemia in Assam Tea Garden Labourers [Correspondence] *Trans Roy Soc Trop Med & Hyg* 1948, Sept, v 42, No 2, 203-5

"The results of treatment with folic acid in 20 severe cases of pregnancy or nutritional anaemia are recorded. As judged by European standards, the final results are anything but normal, but they do demonstrate the life-saving properties of folic acid which should be regarded as a specific drug in this difficult and often fatal condition."

VENOMS AND ANTIVENENES

PRADO, A. & HOGE, A. R. Notas ofiológicas 21. Observações sobre serpentes do Peru [Notes on Ophidia 21. Some Observations on Peruvian Snakes] *Mem Inst Butantan* 1947, v 20, 283-95. 4 figs (1 map) on 3 pls. English summary (2 lines).

BÜCHERL, W. Duas novas espécies do genero *Eupalaestrus* Pocock, 1901 [Two New Species of the Genus *Eupalaestrus* Pocock, 1901] *Mem Inst Butantan* 1947 v 20, 297-314. 8 figs (2 coloured) on 4 pls. English summary.

Butantan* 1947 v 20 31-7 1 graph.

The English summary appended to the paper is as follows:—

"1 By using a purified, electrophoretically homogeneous fraction from the venom of *Crotalus t. terrificus* it has been possible to make a direct evaluation of the combining ratios between venom and antivenom.

"2 As expected from the molecular weight of crotoxin (30-33000) the ratio at the equivalence zone is near 10 i.e. double of that observed for diphtheria toxin (molecular weight 70,000) with equine antitoxin."

EICHBAUM, F W Ação dermatotóxica de venenos ophiônicos e sua neutralização pelos antivenenos. [Dermatotoxic Activity of Ophidian Venoms and their Neutralization by the Antivenenes.] *Mem. Inst. Butantan* 1947 v 20 79-83 English summary

Parenteral injection of the antivenene of *Bothrops jararaca* gives protection against the general toxic action of the venom, but will not prevent the local necrotic effect. In this article the author records his study of the dermatotoxic action of the venoms of *B. jararaca* and of the rattlesnake *Crotalus terr.* in rabbits and dogs. Three types or degrees, of action result from the local application of the venom to the skin: oedema with surrounding infiltration, haemorrhage and necrosis. A study of the different fractions of the venom of *B. jararaca* showed that the fraction producing oedema was different from that producing the haemorrhage and necrosis. The former is not neutralizable by the antivenene even in large doses and is moreover thermostable withstanding heating to 100°C. for 10-15 minutes; the latter is neutralizable (in vitro) by the antivenene and will not resist a temperature of 65°C. for half an hour. If venom and antivenene are left in contact for that time at 37°C., local injection of the mixture prevents the haemorrhage and necrosis but not the oedema.

In the case of *Crotalus* venom, if this be applied to the skin, erythema, oedema and necrosis follow and the [intravenous?] injection of antivenene will not affect this. It is presumed that the concentration is not sufficient, but if local injection of venom and antivenene or even if the antivenene be injected 10 minutes after the venom, prevents the necrosis and the erythema, but not the oedema, just as with *B. jararaca*. The reaction to heat in the case of *Crotalus* venom differs also from that of *B. jararaca*. A temperature of 65°C. for 30 minutes abolishes its necrotizing action; boiling for 10 minutes reduces, may even abolish its power of producing erythema and oedema. H. H. & J. Scott

EICHBAUM, F W O fator de difusão (Spreading factor) dos venenos de *Bothrops jararaca* e de *Crotalus terrificus*. [The Spreading Factor of the Venoms of *B. jararaca* and *Crotalus t. terrificus*.] *Mem. Inst. Butantan* 1947 v 20 95-103 2 graphs. [19 refs.] English summary

In this study the animals used for experiment were white rabbit because their skin is thought to be particularly sensitive in indicating the presence of factor. Four samples of *Bothrops* antivenene and 4 of *C. t.* antivenene and 1 of normal horse serum were used. That the venom of these snakes contains a "spreading factor" has been known for nearly 10 years. The author has found

that this is counteracted by the specific antivenenes. It is, however, enhanced by the addition of horse serum, although the latter by itself has no spreading activity. Since the antivenenes are prepared from horses, the risk is obvious. This serum also fosters the haemolysis resulting from the venom and the transformation of haemoglobin into methaemoglobin. Partly responsible for the spreading may be the property of liberating histamine which is possessed by the venoms and it is known that histamine favours the migration of colloidal particles in the cutaneous tissue. The author remarks, in passing, on the presence of mucinase in the venom, a substance which lowers the viscosity of hyaluronic acid, this test was made on the vitreous body of the eye of the ox.

DERMATOLOGY AND FUNGUS DISEASES

WALSH, E. N. *Tinea Nigra in Panama* *Arch Dermat & Syph* 1948, Apr, v 57, No 4, 732-3

"Tinea nigra (black fungus) of the palm of 3 white North Americans stationed in the Panama Canal Zone is reported. The disease is caused by a black fungus, *Cladosporium werneckii*, is symptomless and is only of cosmetic importance."

HAUSMAN, R. Over Madura-voet en actinomycose in Indië [Madura Foot and Actinomycosis in the Netherlands East Indies] *Geneesk Tijdschr v Nederl-Indië* 1942, Feb 17, v 82, No 7, 307-19, 5 figs on 1 pl [23 refs]

The English summary appended to the paper is as follows —

"Madura foot is a deep, chronic, fungous affection of the foot, in the Netherlands-East-Indies hitherto reported in immigrants (four cases), to which is added a new case, occurring in an Arab.

"Description of three endemic cases in Javanese from East-Java. The fungi did not belong to the actinomycetes, but could not be identified however. One of them probably belonged to *Indiella mansonii* (BRUMPT's white mycetoma).

"From the brief descriptions of twelve new cases of actinomycosis, diagnosed in the past five years at the department for pathological anatomy of the Governments Medical School at Soerabaja, it is obvious that actinomycosis occurs as frequently in the Netherlands-East-Indies as anywhere else. Therefore it is remarkable that up to the present no cases of actinomycotic mycetoma pedis have been recorded in this country."

SASLAW, S. & CAMPBELL, Charlotte C. The Use of Yeast Phase Antigens in a Complement Fixation Test for Histoplasmosis. I Preliminary Results with Rabbit Sera. *J Lab & Clin Med* 1948, July, v 33, No 7, 811-18 [19 refs]

The authors deal with the vexed question of the specific character of the complement fixation reaction when applied to tests with *Blastomyces* and *Histoplasma* antigens and the respective immune sera. They employed as antigens washed, heated suspensions of yeast form cultures of *H. capsulatum* and *B. dermatitidis* and immune sera obtained by inoculating rabbits intravenously with formalized suspensions of the fungi. The injections were given daily for six days and were followed by two or more "booster" injections at intervals of 7 days. Using the Kent and Reip technique of the complement

fixation test they found that cross reactions occurred at relatively low serum titres when these antigens were tested with the heterologous antiserum. By taking quantitative readings, however, they found that the titre of complement fixation was always much higher with the homologous than with the heterologous combinations. For this reason, they recommend that in all diagnostic tests the serum should be tested against both antigens. These findings contrast with those of SALVIN (see this *Bulletin* 1948 v 45 731) who using the Bengtson (wrongly spelled Bengtson) complement fixation technique found no cross reactions between *Histoplasma* and *Blastomyces*. The present authors therefore tested antigens prepared according to Salvin's method, with immune sera using the Kent and Rein technique and found that cross reactions occurred.

Histoplasma antigen did not react with immune sera for *Candida albicans*, *Toxoplasma neoformans*, *Sporotrichum schenckii* or *Paracoccidioides brasiliensis*.

SAGLAM T. Türkiye'de ilk histoplazmozis vakası. [First Reported Case of Histoplasmosis in Turkey.] *Türk Tıp Cem. cii Mecmuası* 1945 Dec., v 11 No. 1. [1 Turkish 494-503, figs. (11 refs. English summary 74-8)]

A fatal case in which *H. capsulatum* was isolated from spleen puncture

LACAS C. de S. & DR. OLIVEIRA E. Blastomycose da região ano-retal. Considerações sobre dois casos. [Blastomycosis of the Ano-Rectal Region. Consideration on Two Cases.] *Hospital* Rio de Janeiro, 1945 June v 33 No. 6 845-54 3 figs. (11 refs.) English summary (8 lines).

Little is known of the epidemiology of South American blastomycosis but it is generally assumed because of the almost constant occurrence of early lesions of the disease on the bucco-pharyngeal mucosa that this is the most frequent portal of infection. The source of the infection, however, has not been proved and in this respect the observations of the present authors are of special interest. After referring to two cases, reported in 1930 and 1940 in which lesions, which may have been primary, were present in the ano-rectal region they describe two new cases with lesions in this area, and point out the probable association of the infection with the use in the toilet of the anus, of leaves and other raw vegetable matter which may carry the fungus *Paracoccidioides brasiliensis*.

When the disease is generalized it may be difficult to decide whether the ano-rectal lesions are primary or secondary to lesions in other parts of the body, but the authors are satisfied that in two or possibly three of the cases referred to the site of infection was the ano-rectal mucosa and the source of the fungus the vegetable material used in the anal toilet.

In treatment sulphadiazine internally and applied locally supplemented by a fungal vaccine proved effective.

J. T. DUNN

HEAT STROKE AND ALLIED CONDITIONS

PELLICCIOTTA, R. Psicosi da colpo di calore. [Psychosis from Heat Stroke.] *Acta Med. Italica*, 1948 July v 3 Suppl. No. 3 120-24. English summary (5 lines).

An interesting case. A man of 32 years, on a ship in the Red Sea, spent a convivial evening with companions and drank several beers. He was

known to indulge fairly freely in alcohol apart from festive occasions. He left them to go to bed. At 5 a.m. he was seen wandering about the deck. He would not speak and did not appear to recognize anyone. He was admitted to hospital. His face was pallid, eyes open, face immobile with an "indefinable smile" and contented expression. He seemed quite oblivious of his surroundings and took no notice when questioned and lay motionless except that his fingers moved as if he were unravelling string. This movement ceased if the hands were held, but began again when they were released. Breathing was calm and regular, pupils normal, reacting to light, patellar reflexes normal, no sign of drunkenness. About 7 a.m. the temperature began to rise and went to 42°C. at 9 a.m. he passed into coma and died at 9.30. The temperature remained up after death [how long is not stated]. The diagnosis from cerebral malaria, epilepsy, dementia precox and other conditions is discussed. The author refers to another case, closely resembling this and also ending fatally, in which the symptoms occurred in an alcoholic. [Unfortunately, no post mortem examination was held, at all events it is not mentioned in this paper.]

H Harold Scott

CHRISTENSEN, W. R. Effects of Physical Characteristics of Fabrics upon Physiological Heat Load and Subjective Reactions. *J Indust Hyg & Toxicol* 1948, July, v 30, No 4, 251-5 [11 refs]

For some textile fabrics physical characteristics, such as their thermal resistivity, have been determined, but for many of the new fabrics used for special military clothing during the war no such data were available. Furthermore, no information was available concerning the physiological load imposed in hot environments by the wearing of garments made from some of these fabrics. The present paper describes the results of an investigation of the physiological heat-loads imposed by some of these garments, and of subjective reactions of the wearers. The tests were made in a climatic chamber under simulated jungle conditions. Air and walls were kept at 90°F, with the wet-bulb temperature at 86°F, and the wind speed was 1.5 or 5.8 miles per hour. The subjects were six to ten soldiers who had been acclimatized to the test environment for one month. The garments tested were U.S. Army fatigue uniforms made from nine test fabrics varying from light poplin or nylon cloths to a cotton herring-bone twill. This latter fabric was of 70 per cent greater weight than the lightest ones. The dry weights of the uniforms varied from 887 gm for the nylon twill to 1,450 gm for the heavier cotton twill. The air permeability of the fabrics varied greatly—from only 2.1 cc per second for a cotton Oxford cloth to 171 cc per second for a Fortisan yarn mesh.

During the experiments, the subjects walked on a horizontal treadmill at 3½ miles per hour for a period of one hour, wearing one of the test uniforms over a standard basic assembly. Rectal temperatures and pulse rates were measured at the end of the exercise, and the sweat loss during the period of exercise was ascertained. The comments of the subjects dealt mainly with coolness, drag, skin sensation and overall preference.

With a wind of 1½ miles per hour, the heat loads imposed by the test fabrics were influenced mainly by their weight, thickness, and possibly by the degree of wetting during use. With a wind of 5.8 miles per hour, however, different results were observed. Then the fabrics which showed improvement with respect to heat load were those which presented a greater wetted area and were more permeable to air. Coolness, general skin sensation, and the tendency of the material to drag on the skin were the most important criteria in deciding the subjective acceptability of a uniform, coolness and skin sensation being of

major importance. There were however inconsistencies between objective and subjective appraisals and it is concluded that the test subjects were unable to differentiate clearly between the sensation of coolness and other sensory impressions.

Thomas Buffin

TROPICAL ULCER

SHILLONG KING EDWARD VII MEMORIAL PASTEUR INSTITUTE AND MEDICAL RESEARCH INSTITUTE 30TH ANN. REP. YEAR ENDING 31ST DECEMBER 1946 (PANDIT S. R. Director) pp. 2-3. Naga Sore Enquiry (Indian Research Fund Association) under the Director

During 1946 eleven patients with "naga sore" (a local variety of tropical ulcer) were studied in the hospital attached to the Institute. All patients were from tea estates. The ulcers were distributed on the lower extremities and were multiple in 4 cases. Seven patients gave a history of trauma and in two the ulcer began on scabies lesions. Blood examination showed evidence of malaria in 2 cases and *W. bancrofti* in two others (without clinical manifestations). One patient harboured ankylostomes and four had other helminths. There were one strong positive and three doubtful Wassermann tests. More than half of those affected suffered from a moderate anaemia, but specific evidence of malnutrition was absent.

The bacteriological flora was characteristic of the usual findings. *Staphylococcus* organisms were constant and in great numbers in the acute stage but decreased with age of the ulcer. *Spirochaetes* were present in four.

In some cases the fusiform organism could be isolated in primary growth, but not in subculture. Growth requirements were studied in detail with two isolated strains. The organism was a strict anaerobe (for primary isolation 5 per cent CO_2 was used, but after a few subcultures an atmosphere of hydrogen sulphide proved satisfactory). The organism was Gram-negative in culture non-motile and pleomorphic. In subculture the beaded appearance was readily demonstrated with Giemsa stain. Colonies were round minute and clear resembling those of streptococci.

The organism failed to liquefy gelatin and to ferment glucose lactose mannite saccharose maltose and salicin. Blood or serum supplements were required to produce growth in carbohydrate medium. Indole was formed. Attempts to prepare agglutinable suspension were not successful. The *spirochaete* could not be cultivated.

Application of the discharge from an active sore did not produce lesions in rabbits or guinea-pigs either directly on the scarified skin or by intradermal inoculation. These methods did however produce typical ulcers, with predominating fusiforms in human volunteers. It is added that in these cases there was also shown the presence of Gram-positive cocci and (in one case) *Proteus*. Intradermal and subcutaneous injection of a young culture of the fusiform organism produced no lesion in a recovered case of naga sore. A killed suspension failed to elicit an allergic reaction in an active case either by intradermal or intraocular inoculation. A small vesicle which retrogressed without resulting in a sore was produced in 24-48 hours in three healthy volunteers after intradermal inoculation of a thick suspension of a culture of the fusiform organism, with or without a filtrate from a discharging sore. The filtrate alone did not produce any reaction.

An epidemiological survey was made of tea estates in the Dibruagarh area of Upper Assam. Seventy-five persons gave a history of having had the sore in 1945. A few still had unhealed ulcers. Forty-one were females (an unusual

preponderance, related perhaps to occupation] All but six were engaged in outdoor horticultural work. The largest number were between the ages of 10 to 30 years there were none below the age of 10, but six were over 50. In one-third of the cases, the ulcers were multiple, and all were on the lower extremities. Thirty-nine persons had a known history of trauma at the site of the lesion (27 cuts, 10 leech-bites, 2 wasp-stings). In the others, itching vesicles and papules were said to have appeared spontaneously. There was no evidence to incriminate any insect vector.

While cases continued during the rainy season in some estates, others with heavy rainfall escaped. Two contiguous gardens had different histories—several cases in one and none in the other. One estate had sporadic cases in 1944, but an almost epidemic form of the disease developed in 1945. New-comers, such as labour recruits, were not more susceptible than older residents.

It is considered that diet plays little part in the aetiology of the disease, which varied within wide extremes of incidence or complete absence over several years despite a diet generally deficient in essential protein and vitamins. It is regarded as of little doubt that the widespread naga sore infection, which occurred over the greater part of Northern Assam in 1942-43 could be traced to the return to their homes of repatriated labourers from infected military camps.

[Although the series of ulcers studied is not large and no striking new information is added to the literature of this elusive disease, the method of approach and the range of investigations carried out at the Institute are to be commended and would well repay repetition in other areas.]

MATHIEU, M. Aluminium et ulcère phagédémique [Aluminium and Tropical Ulcer] *Bull Méd de l'Afrique Occidentale Française* 1947, v 4, No 3, 195-202

This article is based on work done in Dahomey, West Africa, and the author comments on the many different methods of treatment which have been advocated. Treatment with aluminium was first used by a naval surgeon, Brette, in 1939, and, although up to the present the precise mode of action of this metal is a matter of controversy, the results appear to have been very effective. As the author remarks, tropical ulcer is a "veritable plague" in Africa, and by reason of its frequency and chronicity fills up the hospitals and dispensaries.

Eight cases are described in detail, all being typical instances of clinical tropical ulcer. There is no record of any bacteriological or histological examinations having been made.

Although aluminium appears to have a curative effect on the phagedaenic process, its chief use is in the period of cicatrization which is often so prolonged. Among the local inhabitants, the lesion is usually already far advanced and of considerable extent when first seen.

Methods of Treatment

1 Powdered aluminium. The ulcer is first carefully cleansed with ether, aluminium powder then thickly sprinkled on, and an ordinary dressing applied. The powder must be re-applied in not more than three days.

2 Aluminium in the form of a plaque, 1/10 to 2/10 mm thick. This is about the thickness of a piece of notepaper.

The plaque must be moulded to the general contour of the ulcer, and overlap the lesion so as to avoid injury to its edges. It is applied after cleansing with ether, either directly or after powdering with aluminium. Two holes are drilled into the overlapping part, through which pass a fixation tape. It is essential to leave the plaque *in situ* for several days, and this can be used several times; it is sufficient to clean it carefully with ether before each re-application.

Aluminium powder seems to give the better results on account of the closer contact between the metal and the lesion.

Systematically used this treatment has always given good results whatever the condition of the ulcer, cure being assured in a period of 15 to 35 days. From the first application suppuration diminishes, the surface of the ulcer clears, it dries up and takes on a healthy red appearance. Soon epithelium appears at the periphery and filling in and cicatrization progress rapidly from the periphery to the centre.

The advantages claimed are —

1. Simplicity, cleanliness, and rapidity of action.
2. Economy in the use of dressings.
3. Complete tolerance in all cases.

[An interesting paper. This form of treatment would appear to be worth an extensive trial.]

MISCELLANEOUS DISEASES

ORDMAN B. A Review of the Incidence of Hypertension in the Non-European Races. Survey of Blood Pressures in the South African Bantu. *Ch. Pr.* Cape Town 1948 June v 7 No 6 183-210 [37 refs.]

Most of this article consists of a review of the literature on the incidence of hypertension in non-European races. RODDIS and COOPER (*J Amer Med Ass* 1928 v 87 2053) examining a number of European officers stationed in the tropics and on their return to cooler climates concluded that —

- I. Blood pressure is modified by climate.
- II. The indigenous inhabitant of the tropics has a blood pressure lower than that of the temperate zone standard.
- III. In the tropics the systolic pressure of the northern white men averaged 10-15 mm. below the standard of temperate zones, this being due to a lower vasomotor tone and a general slowing of physiological activity.

A study of 774 healthy male Cantonese students by CADBURY (*this Bulletin* 1924 v 21 417) showed that the systolic pressure averaged 20 to 30 mm. and the diastolic 10 to 20 mm. less than in European and American youth of corresponding age weight and height. Hypertension was very rare either with or without nephritis, although Bright's disease was common. Among other reasons for this, the use of opium is given as an explanation. The work of other observers bears this out as regards the blood pressure of the local Chinese. DRELAIDE (*Bull Johns H Hosp* 1940 v 66 408) in 215 cases of essential hypertension, found obesity in 40 per cent.

Blood pressure studies by CONCEPCION and RELATID (*this Bulletin*, 1917 v 9 460) in 697 male and 213 female Filipinos between the ages of 15 and 68 years showed a range pressures 115-79 mm. for males and 117-63 for females. In 65 opium addicts the blood pressure was lower than the average among non-addicts. A comparison by CHAMBERLAIN (*Philippine J Sci B. Med Sci* 1911 v 6 467) of the blood pressures of 329 Filipinos between the ages of 15 and 40 years with those of American soldiers of similar ages stationed in the tropics showed no essential difference between the two groups.

In 500 male Bengalis between 20 and 25 years McCAR (*Lancet* 1907 June 1 1483) found the average systolic pressure to be 90 to 105 mm.

ISMAIL (*Lancet* 1928 Aug 11 275) in a study of over 3 000 Egyptian patients in private practice concluded that —

1. Chronic primary hyperplexus in the absence of chronic renal changes was common and formed at least 10 per cent. of all cases in private clinics.

ii The disease was specially limited to the decades 35 to 55, and was rare under 30

iii About 10 per cent of cases were females

NYE (*Med J Australia*, 1937, Dec 4, 1000) examined all available old people among Australian aborigines, most of whom were grand or great-grand or great-great-grandparents, and found an entire absence of hypertension. It is pointed out that these people live in a state of great simplicity, *i.e.* they do not suffer from the strain of modern civilized life. Gross oral sepsis and cervical adenitis were present, they were heavy smokers and chewers of strong tobacco, and were almost entirely carnivorous. They hunted for their food and gorged only when hungry, often fasting for several days when food was scarce. The question of alcohol is not mentioned.

This observer concluded that age *per se* did not cause hypertension, and that "arteriosclerosis and hypertension may be the price civilisation pays for modern amenities in satiated appetites, sartorial perfection and vitiated atmosphere, and for our successes in a life of stress and strain."

Hypertension in the American Negro has received much attention, and the author quotes from ten papers on this subject. All the writers quoted agree that the incidence is much higher among the negro than the white population, being roughly from two to three times as common. One worker found that the incidence was 6.2 times as high in the age group 30 to 39 years, despite the fact that two hypotensive influences (malnutrition and tuberculosis) were common. The African, when transplanted to modern conditions of civilization, appears less able to adapt himself than his white neighbour.

Investigations by DONNISON [*this Bulletin*, 1930, v 27, 162] of the blood pressure in 1,000 healthy male Africans, aged 15 to 70 years, living at an altitude of 5,700 feet in the South Kavirondo District of Kenya, showed that up to the fourth decade the average readings were similar to those of Europeans, but that there was a tendency to lower readings in later life. Chronic septic infections were common, meat was frequently eaten, but there was an absence of "high pressure" existence.

VINT (*East African Med J*, 1937, v 13, 332) who studied 1,000 consecutive autopsies in Nairobi, states that "True nephrosis as represented by the arteriosclerotic kidney is rare in Kenya. The writer has not seen a case of essential hypertension nor do medical records of the Colony show evidence of its occurrence."

This condition is, apparently, also rare in Uganda.

JEX-BLAKE (*ibid*, 1934, v 10, 286) agrees with Vint, but the author thinks that their conclusions from autopsy studies are questionable.

BECKER (*M D Thesis, Univ Witwatersrand*, 1943, *this Bulletin*, 1946, v 43, 1076), from an analysis of autopsies performed in Johannesburg between 1924 and 1938 concluded that hypertensive heart disease was the most common form of cardio-vascular disease amongst the Bantu and coloured races of South Africa as judged from post-mortem statistics, the condition being found in 247 instances in 3,000 routine autopsies.

Original work is presented by the present author on 1,522 apparently healthy male and female Bantus in South Africa.

Blood pressure readings were taken with a mercury manometer (Baumanometer) with the patient sitting, the effects of excitement and emotion being ignored. The systolic pressure was taken on the appearance of the first sound after deflation of the cuff and the diastolic on disappearance of all sound, readings being taken in the right arm. The following groups were examined—

1 Mine workers returning from an underground shift at a gold mine at Germiston, Transvaal

2 Mine workers and labour recruits being examined in Johannesburg

- 3 Women receiving antenatal examination in Johannesburg
- 4 Rural Africans in the Mafeking District (from three localities).
- 5 Groups of urban and rural Africans in Natal and Zululand, from eight different districts.

A diastolic pressure of over 90 mm. was taken to mean that the subject was either a hypertensive or a hyperreactor and a systolic pressure of over 140 and a diastolic of 90 mm. or less was the criterion of systolic hypertension. No attempt was made to eliminate the factor of emotion or to obtain a modified basal reading at rest. The author considers that a hyperresponse to the excitement of examination is a valuable early sign of the hypertensive process. [Some would consider these figures on the low side.]

Of the total number examined the results were as follow. Of 708 males, 152 showed a diastolic B.P. over 90 and 42 a systolic B.P. over 150 and a diastolic of 90 or under. The corresponding figures for 814 females were 171 and 42. The incidence of a diastolic B.P. of over 90 rose with age but leveled after 70 in males. No racial or tribal correlation was found between those with raised diastolic pressures and the normals in any of the groups. In the case of mine workers, there was no relation between blood pressure levels and periods of work underground. There was an association between hypertension and overweight.

[The literature on this subject is very extensively reviewed. As the African becomes more and more highly educated and more under the stresses and strains of modern life it will be interesting to see in a generation or two how his blood pressure reacts.]

C. F. Shuter

TYNDAL, M. Leber Lathyrismus. [On Lathyrism.] *New York Times*, 1948 Oct 8, v 60 No 40 658.

In the same epidemic at Vapniarka as that described by OXTON [this Bulletin 1948, v 45 735] the author saw 9 cases in men of 16 to 30 years of age who began to show symptoms 2-3 months after starting on a diet consisting very largely of *Lathyrus sativus*. Two were mild cases the others severe. When seen 1½ years after the onset there had been some degree of improvement, but only the two who had been lightly affected could walk without the aid of a stick. All sorts of treatment had been tried—vitamin B in mouth and parenterally, pyretotherapy, passive movements, massage and electrical treatment, baths, liver injections, blood transfusions, nicotinic acid, nicotinamide, arsenicals such as sodium cacodylate and sodium arsenite. It is not possible to say to which, if any of these the improvement was to be attributed but the author thought that the passive movements and the baths and perhaps the blood transfusions all played a part. After two years the gait improved but the chief symptoms remained unchanged. As regards causation apart from the toxic element of *Lathyrus* the general dietetic deficiency and the avitaminosis take a share. Vitamins C and D are present in small amount only in *Lathyrus*—arsenite is thermostable and the prolonged cooking needed to make the *Lathyrus* fit for eating destroys the vitamin B entirely.

D. VITA, J. N. P. Pathology of Central African Natives. *Malaga Hospital Post Mortem Studies*.—VIII. *East Africa Med J* 1948 Aug 35 No. 8 322-6

GUTNER, L. B. & FISHER, M. W. Chronic Meliodosis. Discussion, Case Report, and Special Studies. *Ann Intern Med* 1948 June v 28 No. 6, 1157-68 6 figs. [16 refs.]

This is a detailed report of a case of chronic meliodosis in an American soldier contracted probably in the Philippines. The liver, spleen, lungs and

glands were affected and *Pf whistleri* was isolated from the numerous abscesses which were incised. For some time a diagnosis of infectious mononucleosis was considered, owing to the occurrence of a positive Paul-Bunnell reaction in high dilutions of the patient's serum. The differential diagnosis is discussed. The infecting organism was resistant *in vitro* to streptomycin, penicillin, sulphadiazine and urea, and to combinations of these drugs, in higher concentrations than could be achieved in the blood. This is believed to be only the second case of melioidosis diagnosed in the Western hemisphere.

J C Cruickshank

ARGUELLES CASALS, D. Aftosis generalizada de Touraine (síndrome de Behcet). Primer caso Cubano [Behcet's Syndrome—Generalized Aphthosis of Touraine. First Case described in Cuba.] *Rev Sifilografía, Leprología y Dermatología* Marianao, Cuba 1948, Jan, v 5, No 1, 228-34 [14 refs.]

Characteristic symptoms of Behcet's syndrome are aphthae of mouth and genitalia, ocular lesions such as conjunctivitis, keratitis, retinitis, iritis, phlyctenules, hypopyon cutaneous lesions—nodular, acneiform, pustular eruptions, arthralgia and arthritis, systemic disturbances such as fever and chills in repeated attacks. In some cases the cutaneous and systemic manifestations predominate, in others the mucosal. The cause is not known, but is probably a virus, treatment is unsatisfactory.

The author describes the case of a Cuban woman, 38 years of age, with cutaneous lesions, nodular, red in colour, with undefined edges, in both legs, and oedema of the right ankle, painful aphthae of the buccal mucosa and the border of the tongue, later, similar lesions appeared on the internal aspect of the right labium majus. She had had several attacks during the year, accompanied by severe general pains, headache, fever and giddiness, and lasting 4-7 days as a rule, but sometimes as long as 3 weeks. The Frei and Mantoux tests were strongly positive, Kahn and Meinicke negative. The positive Frei reaction brought up for consideration a diagnosis of lympho-granuloma inguinale, but the usual treatment of this was unavailing and the final diagnosis was Behcet's syndrome, in spite of the absence of ocular symptoms. [Touraine is the name of the author who described this condition in 1941 (*Bull Soc française Dermat et Syph*, 1941, v 48, 61) and has nothing to do with the French Province of Touraine. See also this *Bulletin*, 1946, v 43, 379, 1074.]

CALERO, C. Cutaneous Myiasis in Panama. *J Parasitology* 1948, Aug, v 34, No 4, 343-4.

"The author reports a new case of cutaneous myiasis due to *S. haemorrhoidalis* (Fall) which is reported for the first time from the Isthmus of Panama.

"A first report is made also, but with reservation, of cutaneous myiasis due to *C. hominivorax* (Coq). Our reservation is due to the fact that for Panama there has been no comparative study since 1933 of the larvae originally reported as *C. macellaria* whereas numerous cases of cutaneous myiasis elsewhere reported before 1933 as due to these larvae proved later to be due to *C. hominivorax*."

PROTOZOOLOGY GENERAL

MACDONALD ETTA M. & TATUM A. L. The Differentiation of Species of Trichomonads by Immunological Methods. *J Immunology* 1948 July v 62 No. 3, 309-17 [18 refs.]

The authors have studied the possibility of differentiating three species of the genus *Trichomonas* by serological techniques with the special object of demonstrating the identity or otherwise of *T. hominis* and *T. vaginalis*. The third species used in the experiments for comparison was *T. foetus* of cows.

The serological techniques employed in the experiments were agglutination and agglomeration. The latter term refers to aggregation of motile flagellates with the posterior extremities towards the centre and the flagella of the anterior extremities actively motile at the periphery.

In preparing the immune sera, bacteria-free cultures of trichomonads were used as antigen and rabbits were immunized by intravenous inoculation, the sera being subsequently titrated by a micro-agglutination method. In some of the tests absorption of antibodies in the sera by one or other of the antigens used was resorted to as a preliminary to cross titration experiments both in agglutination and agglomeration.

The results of the various experiments performed may be summarized as follows —

1. Specific antisera prepared against the three species of *Trichomonas* under experiment produced specific agglutination and agglomeration of their organisms.
2. Cross-agglutination and cross-agglomeration tests between *T. hominis* and *T. vaginalis* gave identical results within experimental error but the results were significantly different in the case of *T. foetus*.
3. Absorption of *T. hominis* antisera by *T. vaginalis* removes the antibody for *T. hominis* and vice versa.
4. Absorption of *T. hominis* and *T. vaginalis* antisera by *T. foetus* removes the same amount of antibodies in each case.
5. The results of the various experiments indicate that *T. hominis* and *T. vaginalis* have identical antigenic structure.

CROSS JOY B. & AXIGSTEIN L. Chemotherapeutic Study of Experimental Toxoplasmosis—Preliminary Report. *Texas Reports on Biol. & Med* 1948 v 6 No. 7 280-65 [13 refs.]

This is an investigation into the treatment of experimental toxoplasmosis in mice by six drugs used either alone or in combinations of two. The drugs tested were streptomycin, PARA, (theophylline toluidine blue Sulfamylon and Aralen [Chloroquine diphosphate]. The numbers of mice employed in the experiments were small and the results of treatment showed no significant differences when compared with the results in untreated controls.

ENTOMOLOGY AND INSECTICIDES GENERAL

REYES R. V. Artrópodos de interés médico: eternario comprobados en Colombia [Arthropods of Medical and Veterinary Interest in Colombia. *Rev. Colombiana de Zoonosis Hig. y Med. Vet.* 1947 Oct-Dec 1 No. 10 11-12, 693-721 [Bibliography].

A table of 20 pages.

GÓMEZ, L. Revisión crítica de los casos de oftalmomiasis españolas [A Critical Revision of the Cases of Ocular Myiasis in Spain.] *Rev Ibér Parasit* 1946, Jan-Apr, v 6, Nos 1/2, 51-73, 2 pls [30 refs] [Summary taken from *Rev Applied Entom* Ser B 1948, July, v 36, Pt 7, 119]

In view of a case of ocular myiasis due to *Oestrus ovis*, L., in man in Granada in 1945, the author gives a list of about a dozen such cases that have been recorded in Spain since 1918. The identity of the larvae concerned is not certain in every one, but *O. ovis* appears to be the fly most frequently responsible, though it has sometimes been misidentified, only one case was certainly due to *Rhinoestrus purpureus*, Brauer. The first-instar larvae of these two flies, which have sometimes been confused, are described, that of *R. purpureus* from the work of Portchinsky, and characters are given distinguishing them. The larvae of *O. ovis* observed in Granada and those described by Coulon & Dinulescu from Corsica are considered to represent different varieties, which are distinguished by the form of the spiracles as vars *granatae* and *corsicae*, n

RIDDELL, W A, REMPEL, J G & McNELLY, Elspeth. The Specificity of the Precipitin Reaction, as used in the Study of Mosquito Feeding Habits. *Canadian J Res Sect E Med Sci* 1947, Dec, v 25, No 6, 210-15, 1 pl

The authors have investigated the reliability of the precipitin test when used with the stomach contents of mosquitoes which had been given the opportunity to feed on one, two or three animals. The mosquito used was *Aedes aegypti* and the animals were man, rabbit and guinea pig. The feedings were classified as negative, single (on any one of the three animals), double (on any two) and triple (when fed on all three). With double and triple feeds, the order of the feedings and the time interval between meals were varied. The following table summarizes the feedings and reactions —

Feeding	No of specimens	Total individual feedings	Reactions			Total Errors
			Correct	Missed	Extra	
Unfed	90*	90 [unfed]	90	—	—	0
Single	307	307	287	13	7	20
Double	341	682	652	26	4	30
Triple	6	18	15	3	—	3
Totals	—	1,097	1,044	42	11	53

* This includes 79 unfed *Culex tarsalis* reared from larvae. They gave negative results to human, equine, bovine and avian sera.

These figures indicate a high degree of specificity (95.17 per cent.), the total errors being only 4.83 per cent., the false positives amount to only about 1 per cent. If the negative feedings are excluded, the value of 94.7 per cent. sensitivity for positive reactions is obtained. The figures also disclose that multiple reactions signify multiple feedings, since of double feedings 92.4 per cent. were correct. A point of importance in relation to field work is the fact, that of the 654 mosquitoes known to have fed on one or more of the hosts, 162 specimens showed no distention of the abdomen when killed, yet 91.2 per cent. of the feedings were accurately determined by the precipitin test.

TEIXEIRA A. W. G. A propósito da criação experimental de *Phlebotomus*. [Experimental Rearing of *Phlebotomus*.] *An Inst Med Trop Libor.* 1947 Dec. v. 4 107-48. [25 refs.] English summary

The paper discusses studies in the field and the laboratory on *Phlebotomus* in Portugal. The species captured were *P. perniciosus*, *argutus*, *muscivorus* and *arvensis* with a massive predominance of the former. In the neighbourhood of Lisbon the commonest species is *P. perniciosus* but *P. argutus* was found breeding in one limited area. Specimens of *muscivorus* and *arvensis* were taken but there is no reference in the paper to *P. papatasi*. Most of the biological notes refer to *P. perniciosus*. The adults were first seen in the middle of April, became most abundant or most noticeable in August or September and disappeared in the middle of November. In the laboratory, eggs were deposited from early June to mid-November. The paper contains a number of notes on the proportion of females which had recently fed, the number of eggs laid and other matters. It includes a résumé of the work of other authors on methods of obtaining a culture of *Phlebotomus*. P. A. B. (14)

LABORATORY PROCEDURES

BLACK, R H Haemoglobin Stains adapted for use with Thin Blood Films *Ann Trop Med & Parasit* 1948, Sept, v 42, No 2, 236-7

The author has previously discussed the specificity of staining methods for the identification of haemoglobin in tissue sections [this *Bulletin*, 1948, v 45, 873]. For use in the case of thin blood films these methods require certain modifications. In a previous paper, the author described such a method with the use of cyanol [*ibid*, 1948, v 45, 25]. He now briefly summarizes that method and adds two others, namely (1) alizarin red S and phosphomolybdic acid, which method has been used to study the acquisition of haemoglobin in the maturation of red cells of ducklings infected with *Plasmodium cathemerium* and (2) reduced fuchsin and methyl green, which has been used to observe staining reactions of avian malaria parasites and the changes in haemoglobin content of chick erythrocytes during maturation.

For the first method, blood films fixed with methyl alcohol are stained for 15 minutes with Ehrlich's acid haematoxylin. This is washed off with water and the slides are placed for 1½ minutes in 10 per cent aqueous phosphomolybdic acid. Washing is repeated and followed by staining for 18 hours with a mixture of 50 cc of saturated aqueous alizarin red S and 10 cc of 10 per cent aqueous phosphomolybdic acid. The slide is washed again and dried. Haemoglobin in the red cells stains bright yellow, and nuclei—as in avian blood—are well defined and dark purple.

The second method is stated to give a better contrast between nuclei and cytoplasm of avian erythrocytes than any yet studied. Haemoglobin causes the reduced leuco-form of fuchsin to regain its colour and the haemoglobin of the red cells itself becomes stained with it.

The stock solution consists of a mixture of 1.5 gm acid fuchsin, 5 gm powdered zinc, 2 cc glacial acetic acid and 100 cc distilled water. The mixture is boiled and soon becomes decolorized. On cooling, another 2 cc glacial acetic acid is added. The working solution is made by filtering off 10 cc and adding 1 cc of commercial hydrogen peroxide to it.

Methyl alcohol-fixed dried thin blood films are covered with the working solution, which is left until colour intensity is complete—about 3 minutes. The stain is tipped off and the film is counterstained with 0.5 per cent aqueous methyl green for 1 minute. After a brief wash in water, the slide is blotted dry.

Haemoglobin in normal mature red cells stains with fuchsin and nuclei of avian red cells stain green.

In chick blood infected with malaria parasites such as *P. gallinaceum*, the latter appear as rounded pale green areas in the cytoplasm; the pigment is easily seen. In heavy infections, a series of colour changes is seen depending on the degree of maturation and acquisition of haemoglobin. The cytoplasm of erythroblasts stains green—some show mitotic figures. With further maturation, the green staining is lost and more fuchsin appears in the cytoplasm as the nucleus becomes smaller, more oval and more compact. It is only in those cells in which the cytoplasm takes the fuchsin stain that the *P. gallinaceum* are found.

WOLFF J. W. Een eenvoudige snelle kleuring voor bloedonderzoek op malarieparasieten. [A Simple Rapid Stain for Malaria Parasites in Blood. *Nederl. Tijdschr. v. Geneesk.* 1948 Sept. 11 v. 92 (III) No. 37 2304-7 English summary (4 lines)]

The method, which is a modification of Boyd's method [this *Bulletin* 1946 v. 37 737] is carried out as follows. Films and thick drops are prepared and fixed with methyl alcohol in the usual way and stained with Stévenel's fix for 15 seconds. The stain is then rinsed away with tap water and 1/1,000 eosin solution is applied for 15 seconds. After rinsing with tap water the staining with Stévenel's blue and subsequent rinsing are repeated and the slides are then dried.

ROSENFELD G. Corante pancromico para hematologia e citologia clinica. Nova combinação dos componentes do May-Grünwald e do Giemsa em só corante de emprego rápido. [Panchromatic Stain for Hematology and Clinical Cytology. A New Combination of the May-Grünwald and Giemsa Components in a Stain of Rapid Application.] *Mem. Inst. Butantan.* 1947 v. 20 329-34 English summary (8 lines).

The author claims that this stain is easy to prepare, simple to use, rapid in action, gives more delicate nuclear and protoplasmic delineation than the May-Grünwald, Giemsa or Pappenheim stains, and, lastly, retains its properties unchanged "for many years." Its constituents are as follows: Azure A 0.342 gm., yellow eosin 0.342 gm., methylene blue 0.286 gm., carbonate of methylene blue 0.530 gm., methanol 1 litre. To a blood smear is added 0.5 ml., which fixes it in 1-2 minutes. Distilled water, boiled for 10 minutes and used within a week, is added in twice the amount of the stain and left for 5 minutes or a little longer. The slide is then washed in distilled water and dried with blotting-paper. The longer it remains wet the more it loses colour. H. Harold Scott

REPORTS, SURVEYS AND MISCELLANEOUS PAPERS

COLONIAL OFFICE. Colonial Research 1947-48. Reports of the Colonial Research Committee, Colonial Products Research Council, Colonial Social Science Research Council, Colonial Medical Research Committee, Committee for Colonial Agricultural, Animal Health and Forestry Research, Colonial Insecticides Committee, Colonial Economic Research Committee. Cmd. 7493. 119 pp. 1948. London: H.M. Stationery Office (2s.)

The principal interest of this Report to readers of the *Bulletin* lies in the third annual report of the Colonial Medical Research Committee and the first report of the Colonial Insecticides Committee.

The former occupies some twelve pages and is closely packed with information regarding research problems in being or contemplated, with brief accounts of the activities of the large number of workers engaged upon them. Much of the work referred to has already been noted in papers abstracted in the *Bulletin*.

The Report mentions the visits made by several medical experts to various parts of the Colonial Empire, especially Africa, and refers particularly to measures to be taken to implement recommendations made by the late Professor

McSwiney after his visit to East Africa in 1946. These include the proposed establishment of an East African Bureau of Medical Research, with headquarters at Nairobi, and of a Health Survey to be located initially in Sukumaland, at the southern end of Lake Victoria in Tanganyika Territory.

Reference is also made to the Virus Research Institutes in Uganda and Nigeria, the proposed handing over to the Colonial Office for a research laboratory of the existing laboratory in Freetown maintained by the Liverpool School of Tropical Medicine, research on hot climate physiology in Nigeria and general physiology in Uganda, and investigations of the bionomics of *Ornithodoros moubata* in relation to relapsing fever in East Africa.

Informative reviews are given of research work now in progress. These include the work on malaria control in Borneo, by Dr J McARTHUR, based on his findings of the rôle of *A. leucosphyrus* as a vector; entomological studies on anophelines in East Africa by Dr Murhead THOMSON, who had investigated *A. gambiae* and *A. melas* in West Africa and now reports interesting findings on salt-water breeding of *A. gambiae* in Dar es Salaam; work on malaria control in the Kenya Highlands; studies on Paludrine in Asia and Africa and the question of possible differences in susceptibility to this drug between Asiatic and African strains of the malaria parasite, the results in Africa having appeared to be less satisfactory than in India and Malaya; and a full description of proposals relating to nutrition studies. This includes references to the work of Drs WATERLOW and WEBB on a "pellagragenic" substance in maize bran and on fat metabolism in the liver; field nutrition research in the Gambia where a station has been set up at Fajara and surveys are being made on clinical features, food consumption, crop production, general agriculture, social services and education. Nutrition research is also carried out in other parts of West and East Africa and in Mauritius, the West Indies and the Far East.

Special mention is made of the recommendations of the Nutrition Subcommittee that a section of applied nutrition be formed, with the object of assisting Colonial Governments further in the efforts to improve the nutrition of their populations, and the detailed objects of such a section are set out.

Work on the control of schistosomiasis and of Miracid in its treatment, is discussed. The work of Drs HAWKING and ROSS of the Medical Research Council Scientific Staff and of Dr BLAIR of Southern Rhodesia is mentioned. The MRC has established a team for research on schistosomiasis and its control in Egypt.

Research on filariasis continues and a team is being sent to Africa to study the chemotherapeutic potentialities of Hetrazan. The work will also be applied to *Loa* and *Onchocerca* infections.

The report presents a concise but comprehensive account of medical research projects in the Colonies, and this presentation under one cover provides striking evidence of the wide range of that work, the extent of which is not always either understood or appreciated.

The first Annual Report of the Colonial Insecticides Committee covers 10 pages and is divided into three parts. The first deals with the general organization and terms of reference of the Committee. Its function is primarily to initiate insecticide research, especially its application in field experiments to examine schemes, problems and new scientific information relating to the subject and to advise and, where necessary, reinforce Colonial Governments or other appropriate bodies accordingly, and to co-ordinate agricultural, medical and veterinary interests in the use of insecticides. In the latter connexion, the necessity to consider the effect of insecticides on beneficial insects and the need for knowledge of the ecological problems involved were stressed.

Part II of the Report gives an informative account of the many-sided work of the Committee. It describes the several schemes initiated or sponsored by

the Committee and a number of the experiments referred to are described in considerable detail in part III. Most of the work reported has already been noted in this *Bulletin*. It includes the activities of the Research Unit at Uganda the Colonial Insecticides Team which will shortly start work at Britain at Porton near Salisbury the malaria eradication work in Mawlaikotai Cyprus experiments completed or contemplated with aircraft dissemination of insecticides in East Africa, Zululand and Swaziland the use of helicopters in hilly and other difficult country defoliation experiments disinfection of stationary and airborne craft with non-inflammable and non-corrosive formulations of DDT and benzene hexachloride experiments with smoke generators against tsetse flies and various ecological and agricultural problems. Special notice is given to the Todd Insecticidal Fog Applicator in which the fog is produced by passing the insecticide under pressure into a hot air blast. Work on the *Simal* virus and onchocerciasis is described.

The need for work on insecticide research in Malaya and Nigeria was recognized and while staff cannot be provided at present the Committee is bearing the matter in mind and maintains co-operation with the field workers in an advisory capacity in the former country.

Liaison with overseas workers with various other relevant committees and with other organizations is wide and valuable and this is described at some length.

An appendix lists 13 publications of the Colonial Insecticides Research Unit. Only four of these were actually published the remainder were circulated in mimeographed form (their eventual publication would be of very great value).

The comprehensive nature and range of work set out in this Report amply justify it. Indeed justification were needed, the establishment of insecticide research as an important new and specific branch of disease control in man, animals and plants.

H. J. O'D. Burke-Gaffney

MARTINIQUE. Rapport sur le fonctionnement technique de l'Institut Pasteur de la Martinique en 1946 (MONTESIEUX E. Director) [Report of the Pasteur Institute of Martinique for the Year 1946.] pp 183 + iii.

This Report is divided into five parts. The first gives a statistical analysis of the laboratory examinations for the year. General medical routine investigations amounted to some 40 000. There were nearly 20 000 serological and 8 000 cytological examinations. The second part of the report discusses at some length the various infections encountered. These include intestinal diseases diphtheria malaria, rickettsial diseases, leprosy, tuberculosis and venereal diseases. The incidence of malignant disease is also discussed and there is a detailed discussion of haematological findings. Various other routine investigations are also discussed.

The third part is concerned with research on the enteric diseases anopheline mosquitoes of Martinique general entomology water bacteriology rickettsial diseases and brucellosis. The fourth part gives an imposing statement of the large quantities of biological products provided and the fifth deals with staff and administrative matters. Papers by members of the staff, dealing with some of the subjects mentioned, are listed.

A valuable summary in English of the Report is presented at the end. Points of special interest include the following:—

Typhoid fever is the most important endemic disease in Martinique both quantitatively and in its gravity. There were 399 cases in 1946 of which 360 were confirmed bacteriologically. Except for paratyphoid A and 4 paratyphoid B infections all of these were *Salmon typhi* infections. *Salmon* was found in the infected areas of the island (south and south-east) in 61 cases;

2 each were *P vivax* and *P malariae* infections and the remainder were *P falciparum*. The principal anopheline was *A aquasalis*, which is the local vector of malaria. *A argyritarsis* is also found, but is of little importance as a vector. There were 18 cases of *murine typhus* identified either by *Proteus* or rickettsial agglutination. 13 were from Fort-de-France and 5 from inland areas. Fifty-three new cases of *leprosy* were discovered. Seventy-four *tumours* were found in 236 histopathological examinations, of which half were malignant. Of the *helminth* infections, *Trichuris* accounted for one-third and hookworms and roundworms for about one-quarter each of 7,750 examinations of stools. *S mansoni* was present in 6 per cent. *E histolytica* was only found on two occasions, but *Giardia* was present in 301 specimens. One new case of *Syngamus* infection was found, being the third recorded in Martinique.

The Report is well presented and contains an abundance of information regarding the prevailing pathological and other medical problems in Martinique.

H J O'D Burke-Gaffney

EAST AFRICAN MED J 1948, July, v 25, No 7, 273-80 **The Native Authority Dispensary System in Tanganyika Territory** A Paper read at a Meeting of the British Medical Association of Tanganyika on the 20th February, 1948, by Dr A MCKENZIE, and Record of Subsequent Discussion [McNAMARA, H E, HILL, J F R, JACKSON, E, MCKENZIE, A (in reply)]

The Native Authority Dispensary System was developed in Tanganyika Territory from 1926 onwards as a joint effort by the Medical Department and the Provincial Administration. It was an attempt to give some form of medical attention to the people in remote villages. The Medical Department undertook the training of the dressers, and also acted in an advisory capacity, but finance, discipline and organization were the responsibility of the Administration. Dispensaries were built from Native Authority funds, and the scheme became popular with the people. The dressers were trained to treat minor ailments, and encouraged to send more serious cases to hospital, but by 1930, when there were 288 dressers, it became evident that some of them were attempting work beyond their powers. Increased inspection and more advanced training were instituted in some parts, but reorganization became necessary in view of the general inefficiency. The course of training was extended to 18 months in the Lake Province, where intensive instruction was possible, and to 3 years in other parts where no special teaching staff was available, and where the course consisted of 3 months' classroom work followed by 9 months' practical apprenticeship to an experienced dresser, repeated for the 3 years, or 18 months in hospital and 18 months as apprentice.

The Native Authorities in other provinces began to demand better qualifications in their staffs, and by 1939 it was necessary to review the situation once more. Then the training was concentrated in as few places as possible, and refresher courses were arranged. Nevertheless, the Medical Auxiliaries (as they were now called) did not give an efficient service, and there was a tendency for them to degenerate into dishonesty in their remote stations. This was the position at the end of the war, and McKenzie leaves it there. The question is whether to expand the service, as it has been expanded in the past, or to consolidate and improve the existing service without expansion for the present.

In the discussion following McKenzie's paper, CALWELL made the point that the Medical Department should control the service and that the training of dressers should not be too academic. He agreed with McKenzie on a policy of consolidation. The policy of expansion was urged by Mr HILL, Deputy Provincial Commissioner, who pointed out the need for treatment of people in the remote areas.

Charles Wilcocks

TRAPPEL, C. G. MARTIN J. D. ALLAN W. and other Members of the Department of Agriculture and the Forestry Branch with an Explanatory Memoir by C. G. TRAPPEL. *Vegetation-Soil Map of Northern Rhodesia*. 29 pp. 2 folding maps. 1947. Lusaka, Northern Rhodesia.

The work consists of two sheets of map of a scale of one to a million. It is about sixteen miles to the inch together with an explanatory text. It should be studied in connexion with ecological surveys published by Trapnell for North-west Rhodesia in 1937 and North-east Rhodesia in 1943. The information given relates to distribution of plants (particularly trees and shrubs) and soils in all about fifty types are distinguished. Some reference is also made to the present use of the different types of land. It is not proposed to review these documents. Attention is called to them because of their evident importance in relation to the ecology of tsetse they are probably as important in relation to the distribution of small mammals which is related to possible epidemiology of plague and other diseases. P. A. BAXTER

STRODE G. H. WHAYNE T. F. WILLIAMS L. L., Jr. SAPPERO J. J. & STETTER J. C. *Health Hints for the Tropics. Supplement to Trop. Med. Var.* [1948.] 20 pp. [17 refs.] Bethesda 14 Md. National Institute of Health.

Small publications giving hints on preservation of health, to intending travellers to hot countries are often asked for but not always easy to find. The authors have provided such a concise guide and have been able to condense a remarkably large amount of information in the small compass of 20 pages. They give good advice on climate, water, food, insects and the diseases they carry and immunization and conclude with a section of miscellaneous hints on skin diseases, effects of heat, rest, alcohol, clothing, housing, snakes and dangerous fish.

It is a good and well written pamphlet—very short, of course but full of good sense. Charles W. French

PONACH E. F. *Robert Koch*. 84 pp., 5 figs. & portrait. 1947. Berlin & Leipzig. Volk und Wissen Verlag GMBH. [1 Rm.]

In a book of pocket size (6×4×½ inches) and 84 pages, the author tells the very interesting story of the professional life of Robert Koch and, largely by quotations from a paper by Professor F. A. Heine ("Mit Robert Koch in Afrika und in der Heimat. *Ztsch. f. Hyg. u. Infektionskrankheiten* 1943, v. 125, 265) enables the reader to form some idea of Koch's personality. His outstanding ability was first generally recognized when in 1878 he demonstrated his experimental researches on anthrax to Ferdinand Cohn, the Professor of botany at Breslau University. From that time Koch carried on research in bacteriology and protozoology almost to the time of his death, in 1910. This life-story of constant labour and brilliant discovery at home and abroad is well told in this little book—an index of the persons referred to in the text, a glossary of technical terms and a short bibliography make a useful appendix to the narrative. II YELLOW FEVER

Epidemiology

DE AZEVEDO *et al* (p 1081) found yellow fever protective antibodies in the sera of the people of Portuguese Guinea, but as vaccination has been carried out in the area the significance of these protective bodies was usually doubtful, except in one area where vaccination had not been practised and in which one old person showed protective bodies

LEVI CASTILLO (p 703) has written an account of jungle yellow fever in South America during the period 1932-47, but this cannot be abstracted here

Actiology Animal Hosts Transmission

Because of the shortage of monkeys during the war STÉFANOPOULO and DUVLON (p 252) were led to investigate the effect of various strains of yellow fever virus on the guineapig. Virus 17D killed about 40 per cent of guineapigs when inoculated intracerebrally, and the authors think that these animals may be useful in detecting potential neurotropism, but the rhesus monkey remains the most suitable animal for this purpose

HOCKING (p 72) estimates the prevalence of *Aedes* by placing bamboo "pots" filled with water in the places investigated, and leaving them for 5 days. The number containing *Aedes* larvae provides a good index of prevalence

WADDELL and TAYLOR (p 72) have devised a method for comparing the transmitting capacity of *Haemagogus equinus* with that of *Aedes aegypti* under the same conditions. The ratio of transmission was constantly higher with *Aedes aegypti* than with *H. equinus*. WADDELL and KUMM (p 894) tested the capacity of *Haemagogus capricornis* to transmit yellow fever from infected marmosets, and found that its capacity to transmit by bite was not constant. In general a certain titre of virus in the blood was necessary for infection of the mosquitoes, below this, even though virus was present, infection did not take place.

WADDELL and TAYLOR (p 510) show that although under favourable laboratory conditions certain strains of jungle yellow fever virus may be maintained in marsupials and *Aedes aegypti*, strain differences of the virus may be great enough to affect cyclical passage, moreover, the infected marsupials did not infect mosquitoes which fed on them so well as marmosets. These

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1948 \ 45. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed

result suggest that more evidence is required before the marsupials (*Blasius nudicaudatus* and *Marmosa cinerea*) are incriminated as hosts of the virus: in one field enquiry no evidence was obtained that marsupials play a significant role in propagation of the virus.

CARNEY *et al.* (p. 892) have investigated the distance from their homes to which certain Brazilian monkeys travel. Their normal movements are within a few hundred yards of the home forest and do not explain the rapid and extensive spread of yellow fever through the sparsely wooded areas of Brazil. CARNEY and HUMA (p. 1030) show that when marked forest mosquitoes were released in the forest in Brazil most of those recaptured were taken near the point of release, but some were caught one kilometre away. In another experiment certain species of *Aedes* were captured up to 4.7 kilometres from the point of release: some of these were experimentally proved vectors of yellow fever.

LAEMERT (p. 894) tested the susceptibility of various neotropical rodents to infection with yellow fever virus: some were quite resistant, others showed circulating virus with some strains or developed protective antibodies. Details should be sought in the original.

Investigating the susceptibility of certain species of bats to yellow fever virus HIGGINS and PERLOW-ACORA (p. 810) could not recover virus from 254 bats infected: nor could they detect neutralizing antibodies after the infection.

Immunisation Control

In French West Africa immunization against yellow fever has been combined with vaccination against smallpox, both viruses being reconstituted from the dried state, pooled, and inoculated by scarification. It has been suggested that post inoculation encephalitic accidents occur more frequently after the combined vaccination, and LEPINZ *et al.* (p. 329) have attempted to obtain information by animal experiment, as to the possibility of increased virulence or neurotropism when the viruses are combined. The experiments showed no evidence of this, but as MACCALLUM points out in comment, these results do not settle the problem, because the agent producing post vaccinal encephalitis in man is not known.

Investigations by FOX *et al.* (p. 511) on the duration of immunity after vaccination with strain 17 D have given complete support for the 4 year certificate of immunity which is now in general use.

DE CAIRES (pp. 253-511) describes in detail the extensive organization developed in Georgetown, British Guiana, for controlling *Aedes aegypti* before the advent of DDT and shows how greatly the use of this insecticide has reduced the cost of control and the staff formerly needed. By using it as a residual spray in buildings *Aedes aegypti* has apparently been eradicated in Georgetown. GIGLIOLI (p. 485) has also shown that the domestic biting and resting habits of *Aedes aegypti* in British Guiana render the prospects of control by residual spray with DDT excellent.

LEGIERE RODRIGUES (p. 594) describes the measures taken in Chile especially at Arica, to control *Aedes aegypti*. These include the use of DDT and other measures: inspection of traffic and disinsection of aircraft etc.

MALARIA

HUFF, C G , COULSTON, F , COATNEY, G R , COOPER, W C , PORTER, R J ,
HAAS, V H , WILCOX, Aimee , LAIRD, R L , EWING, Frances M ,
COLEMAN, Nell Symposium on Exoerythrocytic Forms of Malarial
Parasites J Parasitology 1948, Aug , v 34, No 4, 261-320

I Introduction [HUFF] pp 261-3

Once it was known that certain species of *Plasmodium* had exo-erythrocytic stages in their life history, it was natural that active research in this field should be stimulated. This work received added impetus during World War II owing to the need for discovering prophylactic antimalarial drugs acting against exo-erythrocytic stages. It was to integrate the knowledge being acquired on various aspects in this field of research that a symposium was held on the subject.

Exo-erythrocytic stages are well known in certain species of *Plasmodium* parasitizing birds and, in one species, parasitizing lizards.

In the species *P. elongatum*, although cells of the erythrocytic series are preferred by the parasite, it can and does parasitize almost all cells of the blood and the blood-forming cells of the host. In the other species of avian *Plasmodium* which have been adequately studied, cells of the lymphoid-macrophage system are preferred although cells of other types may be parasitized. In *P. mexicanum* of lizards the potencies of both types described above are combined so that the parasite may invade any of the cells referred to.

In the species *P. gallinaceum*, *P. relictum*, *P. cathemerium* and *P. lophurae*, there are pre-erythrocytic stages of development in macrophages or related cells. The first stage developing from the sporozoite is called a cryptozoite and subsequent stages are called metacryptozoites.

If exo-erythrocytic stages exist in human and simian malaria parasites they are relatively fewer and less accessible than comparable stages in avian malaria. Some workers have claimed their discovery while others have searched intensively for them in vain. Indirect evidence of their existence is strong. Thus there may be long periods of aparasitaemia in the blood, followed by patent parasitaemia, and further evidence is afforded by the chemotherapy of the infections.

The discovery of exo-erythrocytic stages has given new lines of approach to chemotherapy by allowing study of the effects of drugs and of immune reactions upon the actual parasites, a procedure rendered easier by their large size. In addition, studies by the tissue culture method have been facilitated since some of the host's cells concerned are easier to grow and to keep alive than are erythrocytes. Other lines of study made possible are the changes produced by altering the species of host, or age of host, by transmitting infections serially from bird to bird through blood inoculation only, by serial transfer of infected brain material from chick to chick, and by similar transfer from chick embryo to chick embryo.

The author utters a warning on the limitations imposed on the contributors to the symposium. The latter gives an incomplete picture and does not answer all questions on exo-erythrocytic stages. It is further emphasized that results obtained with one or more species should not be considered necessarily applicable to all related species and that the findings in avian malaria may not have a parallel in human or simian malaria. The study of malaria parasites should be viewed as a whole and should be combined with consideration of the related genera *Leucocytozoon* and *Haemaphysalis*, which are almost exclusively exo-erythrocytic in their development.

II. A Search for Pre-Erythrocytic Stages of *P. vivax* and of *P. cynomolgi* [E. J. & COULSTON]. pp 284-74 1 fig. [10 refs.]

There is strong indirect evidence for the existence of pre-erythrocytic development of malaria parasites of man and monkeys. While such development has been demonstrated in reptilian and avian malaria, there was [when the author wrote] no conclusive evidence of its presence in mammalian malaria. This uncertainty led to the present investigations from this point of view of *P. vivax* of man and *P. cynomolgi* of the monkey. Although pre-erythrocytic development in these species was not demonstrated, an account is given of the material and methods employed.

In the case of *P. vivax* three strains were employed and in the case of *P. cynomolgi* one strain. For both species *Anopheles quadrimaculatus* was used as the insect host. Mosquitoes infected on man or monkey carrying gametocytes were dissected in a mixture of equal parts of distilled water and serum of the animal to be inoculated and the sporozoites in the glands supplied the material for inoculation. The experiments were divided into those in which *P. vivax* was inoculated into man and monkeys and those in which *P. cynomolgi* was inoculated into *Macaca mulatta*.

In the series of human experiments the following tissues were inoculated with sporozoites from the glands of 6 to 150 infected mosquitoes in each case —

Skin	on 4 occasions
Lymph nodes	7 "
Isolated veins	4 "
Bone marrow	" 2
Muscle	1

The examination of sections of the infiltrated areas for pre-erythrocytic forms was uniformly negative.

Further to verify the absence of pre-erythrocytic forms in the inoculated areas of skin or those subjected to bites of infected mosquitoes, the inoculated and bitten areas were excised and inverted subcutaneously into fresh individuals. None of these became infected although all the donors of skin became so.

Owing to the limitations imposed by human experimental material, attempts were next made to demonstrate pre-erythrocytic stages of *P. vivax* in monkeys. This attempt was based on the authors' demonstration that sporozoites of *P. gallinaceum* and *P. relictum* when inoculated into hosts in which no parasitaemia resulted, might yet produce pre-erythrocytic stages in these uncongenial hosts.

The monkeys used were *Macaca mulatta* *Papio papio* two subspecies of *Cercopithecus aethiops* and *Cercopithecus fuliginosus*. The infective material was inoculated into skin, bone marrow, liver and spleen. Again prolonged search for pre-erythrocytic forms yielded entirely negative results.

In a footnote the authors state that since submission of the paper the publication of the finding of pre-erythrocytic stages of *P. cynomolgi* and *P. vivax* by SHORT and GARNHAM and SHORT, GARNHAM, CORRELL & SWICK [this Bulletin 1948, v. 45, 383-482] led them to a re-examination of their material. With the finding of certain structures they presume to be cryptozoites of *P. vivax* in the liver of *Macaca mulatta*. The description of these must be awaited before comment can be made.

As a final experiment the techniques already used in the case of *P. vivax* were applied to *P. cynomolgi* with *Macaca mulatta* as the host. In this case internal organs as well as more superficial structures were subjected to inoculation of sporozoites. Biopsies made on the spleen, liver, bone-marrow and skin of six monkeys yielded negative results.

In the discussion, the authors emphasize the limitations imposed when working with human subjects, but reach the justifiable conclusion from their experiments that it is highly improbable that pre-erythrocytic stages of *vivax* develop in the skin or in cells of the reticulo-endothelial system, many of which are to be found in the inoculated areas.

The experiments with *P. cynomolgi* and *M. mulatta* were free from the limitations of the human experiments, but, owing to the small number of animals used, are not considered conclusive [see also this *Bulletin*, 1948, 45, 762].

III The Chemotherapy of Malaria in relation to our Knowledge of Exoerythrocytic Forms [COATNEY & COOPER] pp 275-89. [84 refs.]

Since GOLGI's (1893) suggestion that human malaria parasites may, at some stage, develop in cells where they are protected from the action of antimalarial drugs, evidence to this effect has accumulated. [It is stated that the exo-erythrocytic phase in the life cycle of avian malaria parasites was established by American writers between 1944 and 1948, but surely this achievement cannot be taken away from JAMES and TATE who, as the authors state, in 1937, established the existence of the exo-erythrocytic phase in *Plasmodium gallinaceum* (this *Bulletin*, 1937, v 34, 589, *ibid*, 1939, v 36, 339). The subsequent work, often brilliant in conception and execution, served to confirm and amplify the newer knowledge.]

Evidence of the activity of a drug against exo-erythrocytic parasites can come in various ways, depending on whether E E stages are known in the parasite being investigated or whether their presence is merely inferred from indirect evidence.

For a proper understanding of the report, certain terms are defined —

By *prophylaxis* is meant, permanent prevention of erythrocytic infection by drug action against any stage in the pre-erythrocytic cycle.

By *cure* is meant eradication of an established infection.

By *causal prophylaxis* is meant permanent prevention of erythrocytic infection by drug action during the early stages of a sporozoite-induced infection.

Very few workers have described actual morphological alterations of E E forms due to drug action and it is evident, therefore, that discussion on the chemotherapy of exo-erythrocytic stages of malaria must go beyond demonstrable visible effects of drugs on the parasites. There is much of this additional information available from studies on the prophylaxis and cure of both avian and human malarias.

Thousands of potential antimalarial drugs have been tested against various forms of malaria, but comparatively few have shown either curative or prophylactic action. Those which have shown such action, in varying degrees, come under six general categories: quinoline derivatives, sulphonamides, naphthoquinones, biguanides, acridone derivatives and a small miscellaneous group. Seventy-five compounds, discussed in the paper, are listed under these six heads.

From this formidable list, it is evident that the original paper must be consulted for details. These details concern chiefly the chemotherapy of avian and human malaria, since the data on simian malaria is still comparatively scanty.

The conclusions come to may be summarized very briefly as follows —

In avian malarias where E E forms have been demonstrated, some sulphonamides, naphthoquinones, biguanides, acridones, s triazines and a pyrimidine

compound act as causal prophylactics by action against pre-erythrocytic stages. One drug alone, a naphthoquinone, will cure an established infection in which exo-erythrocytic stages are known to occur.

In monkeys with *P. cynomolgus* infections, certain 8-aminoquinolines, with or without quinine, will cure established sporozoite-induced infections.

In human malaria, only the 8-aminoquinolines and the biguanides are active against the hypothetical exo-erythrocytic stages. The former are prophylactic and curative against both *P. falciparum* and *P. vivax*. Palatin, the best known biguanide, is apparently prophylactic against *P. falciparum* and partially so against *P. vivax* but it will not cure an established *P. vivax* infection.

IV The Chemotherapy and Immunology of Pre-Erythrocytic Stages in Avian Malaria [COULSTON & HUFF] pp 290-89 7 figs. on pl. [24 refs.]

Methods devised for studying the *in vivo* action of drugs on pre-erythrocytic stages of *Plasmodium gallinaceum* have been applied and the results are recorded.

Causal Prophylactic drugs

Cryptosporites.—Chickens were given sulphadiazine, sulphamerazine, sulpyrazine, a metanilamide and a naphthoquinone, by mouth in doses much greater than those required to prevent parasitaemia after the introduction of sporozoites. Cryptozoite development was little affected, either in character or in numbers, although in the cases given sulphadiazine, naphthoquinone and metanilamide a few damaged cryptozoites were seen.

Metacryptosporites.—The effect of the same drugs on the metacryptozoites was very marked, as evidenced by cytological changes, lack of development and decreased numbers. It is therefore considered possible that the drug acted on many of the cryptozoite merozoites only when released into the blood.

Suppressive Drugs

Similar methods applied to the suppressive drugs quinine, quinacrine, chloroquine, pamaquine and pentamidine gave different results. All caused morphological changes upon both cryptozoites and metacryptozoites but the proportion of parasites damaged was not so great as with the prophylactic drugs and there was no appreciable diminution in the number of metacryptozoites. The latter developed normally and produced metacryptozoite merozoites even to the extent of an occasional flooding effect. In the latter case small merozoites could be seen on or in erythrocytes and it is presumed that it is at this stage that the suppressive drugs became effective.

In the discussion following the points set out above various aspects of immunity in avian malaria are considered.

In blood-induced infections of *P. gallinaceum* the exo-erythrocytic stages appear late in the infection reaching a maximum by the third or fourth week, long after the maximum of the erythrocytic infection and its decline by which time the bird survives. This difference in time of the maxima of erythrocytic and exo-erythrocytic stages presupposes almost complete independence of the two components of the picture made up by a blood-induced avian malarial infection.

In the case of sporozoite-induced infection exo-erythrocytic forms develop prior to parasitaemia. The transition from these forms to the erythrocytic parasitaemia occurs between the 5th and 8th days and this must be considered the most important event of the life cycle because it enables the parasite to reach a new host via the gametocytes taken up by the insect vector.

These factors have an essential bearing on questions of natural or acquired immunity and on chemotherapy. The next point considered is the natural

immunity of various hosts to pre-erythrocytic forms of *P. gallinaceum*. Thus at one extreme the chicken shows complete susceptibility, while at the other extreme the canary shows complete immunity. Between these extremes, the duck shows partial immunity inasmuch as abundant pre-erythrocytic forms are produced, but no evident parasitaemia follows. The goose, turkey and guinea-fowl show a low grade partial immunity as evidenced by a transient parasitaemia followed by a subpatent infection. All these points indicate the existence of a barrier or threshold between pre-erythrocytic and erythrocytic parasitism and this is referred to as the tissue-blood barrier. In the cases given, it is best exemplified in the duck, where well-developed pre-erythrocytic development is not followed by patent parasitaemia.

The phenomenon of the tissue-blood barrier can be interpreted on the assumption that at least two antigen-antibody complexes are involved. In other words, natural or acquired immunity may be exerted against one or other of the two components of an infection, viz, the tissue stages and the erythrocytic stages.

Thus, in the case of an immunity acquired as the result of inoculation of sporozoites and erythrocytic parasites, the later inoculation of the homologous sporozoites will result in the production of pre-erythrocytic forms although a patent parasitaemia will not follow.

The conclusion is drawn that causal prophylactic drugs produce in susceptible hosts a similar effect to that produced by natural immunity in less susceptible hosts, while suppressive drugs attack the parasite at the point where they are released from the pre-erythrocytic forms to attack the erythrocytes, and therefore act in a manner similar to the tissue-blood barrier.

V Studies in Tissue Culture of Exoerythrocytic Schizogony in Avian Malarial Parasites [PORTER] pp 300-305 [16 refs.]

Attempts to grow exo-erythrocytic forms of avian malaria parasites were made early in the study of these stages.

Most of the earlier attempts at culture, such as those of HUFF & BLOOM [this *Bulletin*, 1937, v 34, 621], GAVRILOV, BOBKOFF and LAURENCIN [*ibid.*, 1939, v 36, 929] and HEGNER & WOLFSON [*ibid.*, 929] gave meagre success in spite of the fact that most of the parasites experimented with have exo-erythrocytic stages in macrophage cells and the latter grow readily in tissue cultures.

Much more successful results were obtained by HAWKING [*ibid.*, 1946, v 43, 410, 1947, v 44, 970] who used flask cultures and material rich in exo-erythrocytic stages. He utilized the technique of JACOBY [*J. Path. & Bact.*, 1944, v 56, 438] in which small coverslips are cemented by plasma clots to the bottom of a Carrel flask. The fragments of material containing exo-erythrocytic forms were cemented to the slips by plasma clots and the covering fluid was Tyrode solution with 20 per cent normal chicken serum and 2-6 per cent extract of chick embryos with the addition of penicillin.

Attempts at subculture gave unconvincing results although the primary cultures were infective to chicks.

Hawking's results have been largely confirmed by ZUCKERMAN [this *Bulletin*, 1947, v 44, 504] and the author of the paper under review. Attempts by various workers to infect cultures of normal tissues with sporozoites have been unsuccessful with the exception of some unconvincing results.

Up to the present time, studies based on the tissue culture technique are in an elementary stage and have supplied very limited information about the exo-erythrocytic stages of malarial parasites.

VI. Response of Exoerythrocytic Forms to Alterations in the Life-Cycle of *Plasmodium gallinaceum* [HAAS, WILCOX, LAIRD, EWING & COLEMAN pp 306-20 3 figs. [12 refs.]

JAMES and TATE in 1938 made the statement that "there is great irregularity in the period of infection during which the exo-erythrocytic stages are developed." Knowledge since acquired has shown that this apparent irregularity is based on varying responses to alterations in the life cycle either natural or artificially produced.

In the present report, three such general patterns of response are described. The first pattern (A) occurs when *P. gallinaceum* is serially transmitted from mosquito to chick. In this case the exo-erythrocytic forms are at their peak about the time when parasitaemia becomes evident. This is the pattern found under natural conditions of transmission; the exo-erythrocytic forms diminishing as the erythrocytic forms increase with the result that the vertebrate host lives long enough to produce the gametocytes which are necessary for the transfer of the infection to another host via the mosquito vector.

Pattern B is seen in chicks infected by blood inoculation and is therefore the parasite's response to an alteration in its normal life-cycle. In this pattern there is a rapidly mounting heavy erythrocytic infection causing the death of a large percentage of chicks. In the survivors exo-erythrocytic development is found about three weeks after the inoculation and often leads to death. A strain maintained in chick embryos by blood inoculation for 180 serial passages over a period of several years showed the same pattern when inoculated into clean chicks. Thus, out of 9 chicks inoculated 8 died of acute parasitaemia and one survived only to die later of exo-erythrocytic infection on the 132nd day after infection.

Pattern C is again the response of the parasite to an alteration of the normal life cycle. In this pattern there is a predominance of exo-erythrocytic forms sufficiently early in the infection to kill the host before erythrocytic forms become numerous or even before they appear at all.

This pattern has been more fully dealt with in the report with reference to the findings in brain-inoculated chicks and chick embryos.

Brain-inoculated Chicks—Brain suspensions containing exo-erythrocytic forms were inoculated intramuscularly into chicks. These chicks show pattern C development, i.e. they die on the 8th to 13th day after inoculation, with heavy exo-erythrocytic development in the brain but with a very mild parasitaemia, if any. The blood from these chicks if inoculated into fresh chicks produced a typical pattern C infection: heavy exo-erythrocytic infection and low parasitaemia. However if the blood was serially inoculated into chicks there was a gradual reversion of the pattern into the first phase of pattern B, with high parasitaemia and death before the appearance of exo-erythrocytic forms. Such converted B strains were very similar to B strains initiated by blood inoculation from the beginning, with the striking difference that there was an almost complete absence of gametocytes. This apparent disappearance must have been only relative because the blood was capable of infecting mosquitoes which were infective to other chickens, producing in them infections of pattern C.

Brain-inoculated chick embryos—The inoculation of infected brain material was made either into the yolk sac or on the chorio-allantoic membrane resulting in infections of C pattern. Embryos killed on the 6th to 12th days showed heavy infections with exo-erythrocytic forms and only mild parasitaemia. The curious feature in these infections was that the erythrocytic parasites were devoid of pigment. When the blood from embryos of this series was inoculated

into clean embryos and the infection of the latter maintained by sub-inoculation, there was a gradual reversion of the C pattern to B pattern in the embryos.

When embryos were infected by means of sporozoites, the C pattern was less clear cut. Thus SHORTT, MENON and IYER [this *Bulletin*, 1941, v 38, 413], in an embryo dying 11 days after sporozoite infection, reported an extremely heavy exo-erythrocytic infection and a moderate parasitaemia, so that an earlier examination would probably have revealed exo-erythrocytic forms before the appearance of any parasitaemia.

HAAS and EWING [*ibid*, 1945, v 42, 539], in embryos infected by mosquito bites, found infections resembling pattern A in some and pattern C in others, while in some an intermediate condition was found in which heavy parasitaemia and many exo-erythrocytic forms were simultaneously present.

When chicks are infected by sporozoites taken from mosquito-chick passages, pattern A infection develops, but when the sporozoites come from chicks of the blood-inoculated series, pattern C infections ensue.

It is thus seen that the pattern of infection is chiefly dependent on the source of the sporozoites.

Finally, it has been shown that C pattern of development can be obtained by suppressing erythrocytic forms by quinine and then maintaining the infection in serial passages.

H E Shortt

[For a full discussion of exo-erythrocytic schizogony in malaria, see also GARNHAM, this *Bulletin*, 1948, v 45, 831.]

CANAPERIA, G A & PATRISSI, T. La malaria in Italia nel periodo bellico e post-bellico. Considerazioni epidemiologiche e misure profilattiche [Malaria in Italy during the War and the Post-war Period. Epidemiology and Prophylaxis] *Riv di Malariaologia* 1948, Feb, v 27, No 1, 1-28, 8 figs & 1 map. English summary (4 lines).

This paper describes the trends of malaria morbidity and mortality in Italy since the beginning of the century, the excessive malaria mortality that marked the close of the first world war, the rapid decline in malaria morbidity that occurred during 1935-39 to the lowest level ever recorded, and the subsequent spectacular rise in malaria incidence. In 1945, there were recorded 49,731 primary infections and 362,376 relapses as compared with 55,453 total cases in 1939. Energetic measures are once more bringing the disease under control. Early trials with DDT have produced remarkable results and the widespread use of DDT is the outstanding feature of the five-year programme of control that has been adopted by the public health authorities.

Norman H Hut

JAFAR, M & IYENGAR, M O T. The Incidence of Malaria in a Deltaic Area of Lower Bengal between the Damodar and the Hooghly Rivers. *Indian J Malariaology* 1947, Dec, v 1, No 4, 441-67, 1 map.

This is a report of a malaria survey of a flat deltaic area of Lower Bengal comprising parts of the three districts, Burdwan, Hooghly and Howrah. There is a slight fall in the general ground level from north-west to south-east. The elevated parts have fairly effective natural drainage and contain no extensive collections of water, in spite of an annual rainfall of about 55 inches. The lower portion has very little natural drainage and contains extensive areas that hold water for several months of the year. Between November 1945 and February 1946 372 villages were surveyed and 25,632 children were examined. The overall spleen rate was 34.1 per cent. The proportion of plasmodial species in 87 positive blood smears was *P. falciparum* 62, *P. vivax* 28 and *P. malariae* 10.

Species of adult *Anopheles* captured in order of frequency were *A. souleyi*, *A. vagans*, *A. pallidus*, *A. acuminatus*, *A. hyrcanus* var. *nigerrimus*, *A. namusari*, *A. philippinensis*, *A. s. byssus*, *A. barbrostris* and *A. culicoides*. *A. philippinensis* is the chief malaria vector in Lower Bengal. It was found breeding in ponds with subaquatic vegetation and fairly clean water.

Malaria was very unequally distributed. The average spleen rate in the elevated dry areas was from 47 to 63 per cent. The low water-logged areas were comparatively free from malaria. In one of them the spleen rate was only 4 per cent. These results confirm the finding previously reported by BINGHAM that a high subsoil water level acts as a deterrent to the breeding of *A. philippinensis* [this Bulletin 1943 v 40 683 1945 v 42 625].

The area was surveyed in connexion with a proposed Damodar Flood Flood Control Scheme designed to improve agriculture by irrigation and drainage. The raising in the water table that is likely to result in parts of the area should result in a reduction of malaria prevalence. VAN DER PLIGT

YACOB M & SWAROOP S. Malaria and Spleen Rate in the Punjab. *Indian Medical Journal* 1947 Dec. v 1 No 4 460-69 3 charts

Every year since 1914 a spleen examination of male school children between ten years of age has been carried out in all parts of the Punjab in June before the beginning of the malaria season and in November toward the close of the malaria season. Some 68,000 children attending 490 schools in 270 localities have been examined each year. The very large mass of statistical information provided by these annual spleen surveys has been examined by the authors. They have not been able to show that fluctuations in spleen rates have any value in forecasting the incidence of malaria. (GILL advanced the view that a low spleen rate in the month of June, provided the other factors are favourable, is regarded, so far as communal immunity is concerned, as favourable to the occurrence of an epidemic during the ensuing autumn. See also this Bulletin 1945 v 42, 620.) VAN DER PLIGT

VAN GOOR, W. T. Onderzoek naar de miltvergroting bij schoolkinderen in het ressort Tjandjoer (April-Juni 1947) [An Investigation into Spleen Enlargement in Schoolchildren in the Province of Tjandjoer (April-June, 1947)] *Med Maandblad Batavia* 1948, Juli 1 v 24 473-83 1 map.

During the Japanese occupation of the Netherlands East Indies the anti-malarial measures in the province of Tjandjoer had been almost entirely relaxed. Much ground had been allowed to become fallow, vegetation was not cleared and planting regulations especially as regards rice together with irrigation schemes had fallen into disuse. Conditions were thus ideal for the breeding of *Anopheles acuminatus* and the spread of malaria.

It was decided to carry out a survey of spleen enlargement in schoolchildren in an attempt to assess the present prevalence of malaria. Some 3,600 children were examined in 52 localities and the spleens classified as absent (small—half way to the umbilicus), moderate (reaching to the umbilicus) and "large" (below the umbilicus). The proportions over the whole province were —

Absent	1,522 cases	40 per cent
Small	115	30
Moderate	973	28
Large	151	4

The average splenic index was thus 60 per cent For boys the index was 60 per cent, for girls 52½ per cent (only 3,116 cases were available for analysis)

The splenic index varied considerably in different parts of the territory On the high ground (up to 1,200 metres) it was of course lower, but even here reached 24 per cent In some areas, however, it reached 100 per cent

These figures are compared with previous years for certain areas For those where complete figures are available the average splenic indices were —

1919	1922	1931	1941	1947

ANDREWS, J M What's happening to Malaria in the U S A ? *Amer J Pub Health* 1948, July, v 38, No 7, 931-42, 5 figs [40 refs]

The general decline of malaria in the U S A began during the last quarter of the 19th century Then the disease was widespread over the eastern two-thirds of the country During the present century the declining incidence has been interrupted every 5 to 7 years by seasons of increased transmission The last of these cyclic waves of increased transmission occurred in the mid-1930's By then endemic malaria areas had contracted to the south-eastern States Since that last period of enhanced transmission, malaria prevalence has steadily and continuously declined in the U S A The author considers in turn the possible influences that may have determined this remarkable downward trend

There has been no deterioration in the potentialities of the parasite-host-vector system of malaria transmission during the last twelve years changes have been quantitative rather than qualitative In certain areas, antilarval measures may have diminished malaria endemicity but it is doubtful whether such measures were primarily responsible for the regional decrease The reduction of domestic densities of anophelines by insecticides, by insect-proofing of houses and as a result of anopheline deviation by cattle is probably a more important causal factor Population movements from endemic areas of the south to malaria-free areas, and improved antimalaria medication have contributed to the decline Economic advance has stimulated the development of most of these factors

Control techniques are continually being improved If advantage be taken of the present favourable conditions, the complete eradication of malaria from the United States is within the bounds of possibility

GREENWALD, Margaret, COCHRAN, J H & SCHARFF, D K Large-Scale Rearing of *Anopheles quadrimaculatus*, Say, at Orlando, Florida *Mosquito News* 1948, June, v 8, No 2, 50-56, 6 figs

In this paper the authors give a complete description of their equipment and methods of management of a large successful laboratory colony of *Anopheles quadrimaculatus* at Orlando, Fla., which is capable of a daily output of 40,000 adults, 5,000 larvae and over 100,000 eggs This colony has been developed from the original methods described by Boyd *et al* in 1935 The reader is given all information he is likely to need as to the sizes and kinds of equipment and the various daily routines Such detail cannot be summarized but the following points are of particular interest

In addition to an indoor unit totalling 975 square feet there is also, at Orlando, an outdoor unit of 40 rearing boxes maintained in a stream The authors have found that the ideal temperature for larval development is 80 to 82°F (26.5 to 27.5°C) and that exposure to daylight is not essential It is extremely

important that the amount of food given to the larvae, and the feeding time, should receive special and continuous attention. The cages of adults which are kept at 84 F (29°C.) should be protected from draughts, bright light and extremes of temperature. At Orlando the natural humidity is so high the humidity control in the insectaries is unnecessary. Eggs can be stored in a ice-box, where they remain viable for ten days. Some of the equipment and procedures are illustrated by photographs.

NOZ, J. & MANN F., G. Disminución Invernal del anofelismo en Tarapacá (Great Reduction in Winter of Anophelines in Tarapaca, N. Chile). *Patologica* Santiago 1948 Dec. No. 5 3-12, 4 figs. on 2 pls. English summary

In the region of Tarapaca in Northern Chile, rain falls in the summer and *Anopheles pseudopunctipennis* breeds in the streams. With the advent of cold weather the rains cease and the streams dry up becoming a series of isolated pools. Perhaps because the water is stagnant the filamentous algae which appear to be the principal food of the *Anopheles* larvae die and masses of dead algae become invaded by putrefactive bacteria. Water becomes so foul that *Anopheles* larvae and many other insects and other organisms are killed in large numbers.

After winter when the temperature again begins to rise ice melts in the upper Andes so that the streams begin to run again. The filamentous algae grow and an abundant population of *Anopheles* larvae appears. We have endeavoured to summarize the facts; the authors have worked out an ingenious explanation which involves a consideration of water chemistry and many other matters.

CLÉMENT R., GERBEAUX, J. & SATGE P. Trois observations parisiennes de paludisme acquis du nourisson. Endomyopéricardite dans un des cas. (Three Cases of Acquired Malaria in Infants in Paris: Endomyopercarditis in One Case.) *Bull. et Mém. Soc. Méd. Hôpitaux de Paris* 1948 Nos. 24/25 889-896 1 fig. [24 refs.]

The three cases of malaria described concerned infant of two, six and eleven months of age respectively. The first had recently arrived from the Cameroons but the other two had never been away from Paris. All three cases presented diagnostic difficulties. The youngest child had symptoms of acute enteritis and it was only on the ninth day of illness that *P. vivax* was found in the blood; he recovered. In the second child *P. falciparum* malaria complicated a diphtheritic rhinopharyngitis; the diagnosis of malaria was made too late to avert a fatal issue.

The third child died with endocarditis, myocarditis and pericarditis and a heavy infection of *P. falciparum*. Section of the myocardium showed an abundance of malarial pigment. Haemocultures had been constantly negative. A normal sedimentation rate and the blood counts appeared to negative a septicæmic origin of the cardiac lesions. The occurrence of a *P. falciparum* infection in an infant who had never been outside Paris is in itself a very liable happening.

HANNS, A & MUGLER, A Le paludisme des rapatriés de Russie. Son apparition tardive Sa latence intercalaire [Malaria among Persons repatriated from Russia - Its Late Appearance and Prolonged Latency] *Bull et Mém Soc Méd Hôpît de Paris* 1947, Nos 34/35, 1033-7

The authors have had in their hospital in Alsace 26 patients suffering from *P vivax* malaria which had been contracted several months or a year previously in Russia. These men had been impressed into the German army, been made prisoners by the Russians and most of them had been interned in the concentration camp at Tambov where they had passed a year or eighteen months. Tambov is in a marshy malarious area near the centre of Russia. They were repatriated in the autumn of 1945 in a miserable condition. Their condition steadily improved after their return home till the return of the warmer weather, when malaria suddenly attacked them. In only 8 of the 26 cases was there any history of febrile episodes that might possibly have been caused by malarial infection.

The authors discuss the possible reasons for the prolonged latent periods in these cases and for the fact that few or any of them had suffered from clinical malaria in Russia. They advance the hypothesis that their state of extreme debility and malnutrition may have been responsible, it was only when they had regained a more normal state of health that their bodies were able to react against the malaria parasite.

Norman White

HANNS, A & MUGLER, A Le paludisme des rapatriés de Russie (Deuxième communication) [Malaria in Persons repatriated from Russia] *Bull et Mém Soc Méd Hôpît de Paris* 1948, Nos 24/25, 818-21

The authors describe difficulties in diagnosis that have been experienced in the case of sufferers from malaria who have been repatriated from Russia to Alsace where there is no endemic malaria. Many of these have been primary attacks of malaria after prolonged incubation periods. For the most part the cases have been mild. Certain patients with disquieting renal, cerebral or hepatic symptoms had organs that had been damaged by previous disease. The symptoms were protean. Lumbar pains sometimes extremely violent, severe headache, irregular fever, and dissociation of pulse and temperature were frequently observed. All infections were due to *P vivax*. Clinical attacks yielded promptly to quinine or mepacrine.

Norman White

MARCHIONNI, M Un caso di rottura spontanea della milza in malarico [A Case of Spontaneous Rupture of a Malarial Spleen] *Riv di Malariaologia* 1948, Feb, v 27, No 1, 41-6 [11 refs] English summary (2 lines)

This describes an unusual case of rupture of an enlarged spleen, the occurrence of which was not suspected until laparotomy revealed the true state of affairs. On admission to hospital the patient must have had a small subcapsular rupture of the spleen, which was not diagnosed. This haematoma seems to have enlarged slowly during the following night, causing the spleen capsule to rupture while the patient slept. The symptoms then suggested the perforation of a gastric ulcer, the pulse rate was only 90. When operation disclosed the nature of the lesion the patient's condition was too grave to allow splenectomy to be attempted. The laceration was sutured and plugged, and a drainage tube left in. The patient eventually recovered.

MADRAS GOVT OF Soil Erosion—its Prevention and Control. pp. 22 14
158 figs. & 1 folding map. 1948. Madras. Govt. Press. (6 rupees.)

This book, compiled by the former Chief Engineer for Irrigation and the Heads of the Departments of Irrigation, Agriculture Forestry and Public Health, Government of Madras is intended primarily for departmental use and for teaching agriculture and forestry. Most of the figures are from photographs taken in Madras the United States of America and other countries.

In the final chapter on erosion and malaria, it is pointed out that the problem of erosion and its control is in fact one of regulating the flow of water and therefore has an important bearing on malaria. After an introductory account of malaria and its transmission some effects of erosion are mentioned by making ground uneven and by promoting scouring and intermittent flow in streams it causes pools to form and by increasing run-off from hills it flows lower land. An account of engineering methods of mosquito control, familiar to malarialogists follows. On page 153 varieties of mosquitoes would better be written as genera, and on page 160 the filling of all points perhaps refers to ponds.

To medical officers of health the main body of the book should be useful in showing what is being done to check erosion. They can then foresee any consequent increase of potential breeding places of mosquitoes for example in water held up by certain types of terraces and dams and can plan control measures accordingly.

D J Lewis

FLETCHER, O. K. Jr. Ducks as Mosquito Predators. *J. National Malaria Soc.* 1948 Sept. v 7 No 3 183.

During routine malaria control inspections on a plantation in Dougherty County Georgia, in the summer of 1946 the author noted that a certain pond had a particularly dense population of mosquito larvae especially those of *Anopheles quadrimaculatus* and, to a lesser extent of *A. crucians* and others. The pond measures some 1.5 acres in extent and the whole surface is covered with vegetation and floatage, thus lending itself readily to larval survival. Throughout the summer larval densities in this pond increased to a maximum of 35 per square foot of breeding area on October 1st.

A few days later a flock of 63 large white Peking ducks were turned into the pond to graze. At the next inspection ten days afterward not a single mosquito larva and no edible floatage could be found. It was evident that the duck had performed a thorough job of eradication and no more larvae were found as long as they remained there.

The persistence of large numbers of larvae in comparable ponds excludes seasonal decline as an explanation. Furthermore no larvicides had been applied to the pond during 1946. As this pond is the only important one within flight range of human dwellings on the plantation it would seem that the feeding activities of the ducks had made "an appreciable contribution to malaria control."

The only reference to such activities which the author has been able to find has been in a current naturalist's publication where it is stated that the Mallard Duck ingests substantial quantities of mosquito larvae. The present author points out however that predation of wild ducks on mosquito larvae are of little significance in the malarious regions of the south, since their sojourn there is largely restricted to the winter months. [But the use of such ponds, when they are present by domestic ducks might well be encouraged.]

FLORIS, M. Relazione sulla campagna antimalarica 1947 nella Provincia di Cagliari [Antimalaria Campaign of 1947 in the Province of Cagliari] *Riv di Malariaologia* 1948, Feb., v 27, No 1, 29-40, 5 charts & 1 map English summary (3 lines)

The detailed description of the antimalaria campaign of 1947 in the Cagliari Province, Sardinia, is of more local than general interest. Malaria prevalence was remarkably lower than in the previous year. In 1947 there were recorded 6,062 cases of malaria, of which only 993 were fresh infections. In 1946 there were 17,135 reported cases, of which 3,380 were fresh infections. Another remarkable contrast with previous years was the greater prevalence of *P vivax* than of *P falciparum* infections, positive *P vivax* films numbered 823 as compared with 611 *P falciparum*. These results are attributed to the DDT treatment of houses. It is interesting to note that fresh infections were most numerous in 1947 in the months of July and August. At this season agricultural activity is at its height and many country folk spend the nights in open country without any protection against the attacks of mosquitoes.

BALL, E. G., MCKEE, R. W., ANFINSEN, C. B., CRUZ, W. O. & GEIMAN, Q. M. Studies on Malarial Parasites IX Chemical and Metabolic Changes during Growth and Multiplication *in vivo* and *in vitro* *J Biol Chem* 1948, Sept., v 175, No 2, 547-71 [23 refs]

This series of papers deals with the growth and multiplication of malarial parasites. The present report describes the chemical and metabolic changes which have been observed in the red cells of monkeys during the growth of *P knowlesi* *in vitro* and *in vivo*. Some of the results confirm those of earlier authors [For summaries of preceding papers, in which the techniques employed are described, see this *Bulletin*, 1945, v 42, 867, 1947, v 44, 17, 649, 1043]. The changes occurring have been based on those taking place in a standard number of red cells, and are correlated with both the number and size of the parasites present. As other authors have pointed out, parasites grown *in vivo* caused a large rise in glucose and oxygen consumption over normal red cells but it has not been observed to the same extent with parasites grown *in vitro*. The ratio of moles of glucose to moles of oxygen consumed was approximately unity. The glucose was mostly converted to lactic acid. There was a more constant rise in fatty acid and in the various phosphorus fractions in parasitized cells grown *in vivo* than in those grown *in vitro*, which the authors believe may be explained by the lack of certain nutrient factors in the culture medium. The increase in nucleic acid phosphorus partly identified as of desoxyribose type was noteworthy. It is believed that *in vitro* the parasite can synthesize nucleic acid from certain components if supplied, but whether it can synthesize all the purines and pyrimidines has still to be determined. Experimental evidence does suggest that adenine can be synthesized. It was not clearly determined whether the co-enzyme flavin-adenine dinucleotide was synthesized by *P knowlesi* *in vitro*, since normal monkey cells in similar circumstances can synthesize this substance. The generally accepted view is that the parasite converts at least some haemoglobin of the host cell to haematin. Quantitative estimations have shown that during its life cycle *in vivo*, *P knowlesi* destroys nearly all the haemoglobin of the host cell and retains the haematin formed. Comparable results were obtained *in vitro*, but in neither case was the mechanism of the degradation determined.

J. D. Fulton

out that a similar potentiation of effect would be of great value in bacterial infections and in human malaria. [These results obtained by combined therapy of paludrine and sulphadiazine are of great interest when considered in conjunction with the experiments of BRADY & MCCORMACK (see above) who found that a sulphadiazine-resistant strain of *P. gallinaceum* developed simultaneous resistance to paludrine. They also found that a strain long resistant to paludrine and maintained in contact with that drug was likewise resistant to sulphadiazine. The evidence so far available suggests the long contact of *P. gallinaceum* with paludrine was necessary before resistance to sulphadiazine develops.]

BRUM, D. L. Experimental Transmission of the "3M" Strain of *Plasmodium cathemerium* to the Duck and its Chemotherapeutic Suitability for Routine Antimalarial Screening. *J. Parasitology* 1948 Aug v 34 No. 4 531-533 graphs. [28 refs.]

The strain of *P. cathemerium* described here, which had previously been maintained in canaries was found to adapt itself readily to the duck host, but not to the chick. When 10^4 parasites per gm. weight were given intravenously the peak of parasitaemia occurred on the 4th day. The infection showed considerable virulence and produced marked anaemia, but virulence was not increased by more than 300 passages. Periodicity was of 24 hours duration and marked synchronicity was exhibited on the first and second day of infection but not around the peak of infection. The number of merozoites per segment on the 4th day was 6 to 24 with a mean value of approximately 12. There was marked destruction of parasites around the peak period and thereafter parasites rapidly disappeared from the blood. Erythrocytic stages of the parasites could not be demonstrated. In therapeutic tests the drugs were administered in the food and the birds were kept on a 4 hour light and dark schedule. Treatment was started 24 hours before intravenous injection with 1.5×10^4 parasites per gm. weight. The strain was not susceptible to sulphadiazine. The morphological changes induced in the parasites by standard drugs and others are described. It is suggested that the duck is a suitable host for use in antimalarial screening tests with this strain of parasite.

BLACKWATER FEVER

POURSIRES Y & MOUTARDEUR, G. Lésions histologiques de rein dans la fièvre bilieuse hémoglobinurique. Contribution à l'étude du mécanisme de l'anurie. Déductions thérapeutiques. (Histological Study of the Mechanism of Anuria in Blackwater Fever and its Therapeutic Implications. *Bull. Soc. Path. Exot.* 1948 v 41 Nos. 7-8 553-8.

One of the authors recently studied blackwater fever in French Equatorial Africa. In most of the cases discussed blackwater fever appeared during an exacerbation of chronic malaria. The clinical picture was characteristic—oliguria developing into anuria with final uraemia. In one case there was persistent severe anaemia with normal kidney function.

The histological work described in this paper is based on the examination of tissues from three patients who died in uraemia. About 10 to 15 per cent. of the uriniferous tubules contained compact plugs of a brown red mass staining brick-red with eosin and containing no free iron. These "plugs" were common in the excretory part of the tubules but were not seen in the

secreting portion where there was only some protoplasmic debris or an eosinophilic substance which was very little condensed. A striking feature was the retraction of the glomerular tufts with a corresponding apparent increase in the size of Bowman's cavity. In some glomeruli there was a cubical change in the epithelium of Bowman's capsule. The authors were struck with the absence of mesenchymal inflammatory lesions, either acute or chronic. There was venous congestion and oedema of the medulla and the renal blood vessels contained few red cells which were often "*perdus dans une substance hyaline*".

The authors conclude from the fact that the majority of the renal tubules appeared to be open and not obstructed by "plugs" that the "blockage" theory of the pathogenesis of anuria cannot be maintained. They suggest that the retraction of the glomerular tuft follows a vaso-constriction within the tuft, presumably reflex, which results in the failure of the filtration of plasma across the glomerular membrane. This failure of filtration would account for the anuria.

On the grounds of the possible reflex origin of anuria, the authors recommend the use of intravenous novocaine (without adrenaline) in oliguric and anuric cases. They suggest two or three injections of 5 to 10 ml of 1 per cent novocaine given slowly in the course of 24 hours. Hypertonic saline (10 per cent) may be administered simultaneously. In cases where this fails to produce diuresis, direct "infiltration" of the renal "pedicles" is suggested.

The authors state that intravenous novocaine has given extremely good results in cases of anuria. All cases cannot be cured by this method, but they believe that in blackwater fever, where anuria is so often fatal, this physiological therapeutic method should be used as a routine, accompanied by anti-haemolytic treatment.

[It is not quite clear whether the authors are referring to their own results in the treatment of renal complications of blackwater fever, or whether they are making a general statement when they say that intravenous novocaine has relieved cases of anuria. If they are indeed referring to blackwater fever, this paper is important because it is the first report of such treatment in that disease. The suggestion that the "renal pedicles" should be "infiltrated" seems rather drastic.]

The authors make no reference to the very large literature on the subject of acute renal failure which has accumulated in the last decade. The theory of renal anoxia, so like their own, appears to be unknown to them.]

B G Macgregor

LANGUILLON, J. Le facteur Rh dans la fièvre bilieuse hémogloburique [The Rh Factor in Blackwater Fever] *Bull Soc Path Exot* 1948, v 41, Nos 7/8, 470-73

The author discusses the theory that the Rh factor is concerned in the pathogenesis of blackwater fever [see this *Bulletin*, 1946, v 43, 533]. He points out the similarity between the clinical and pathological pictures of incompatible transfusion and blackwater fever, and refers briefly to the evidence supporting the view that the malarial plasmodium may act as an antigen. He suggests that the malaria parasite contains a substance capable of sensitizing Rh negative individuals in the same way as in transfusion with Rh positive blood, or an Rh positive foetus. This sensitization is increased by repeated attacks of malaria and eventually sets off a haemolytic crisis which appears clinically as blackwater fever. His arguments in favour of this theory are as follows — (a) Four settlers in the New Hebrides who developed blackwater fever were all Rh negative. (b) Blackwater fever is unknown amongst the indigenous population of the New Hebrides, all of whom, according to the author, are Rh positive.

(c) Cases of blackwater fever occurring in the same family could be explained on the grounds of the hereditary transmission of the Rh factor. Two examples of multiple cases of blackwater fever in one family are reported.

In the discussion following the presentation of this paper there are very interesting comments. GIRAUD pointed out that something like 800 aborigines had been examined and were all Rh positive. DISCOMCK thought the presence or absence of the Rh factor in human blood could not by any means be the cause of the development of blackwater fever. For example there was no blackwater fever in North Africa where malaria was highly endemic and the incidence of the Rh factor was the same as in countries where blackwater fever occurred.

B. G. Macdonald

TRY PANOSOMIASIS

FORD J. WHITESIDE E. F. & CULWICK A. T. The Trypanosomiasis Problem. Reprinted from *East African Agric. J.* 1948, Apr. v. 13 No. 4 187-241 (18 refs.)

The authors examine the problem of African trypanosomiasis as a whole. They recognize three lines of approach, through the trypanosome, the tsetse and by way of a broad ecological view. They try to avoid prepossessions, and have produced a valuable stimulating paper which has a new look.

The authors enter the subject by summarizing what is known of the trypanosome and the tsetse and calling attention to what is involved. They are interested in the possibility of immunizing against trypanosomes though the difficulties are stated. They emphasize the need for thinking quantitatively about fly populations and are prepared to discuss measures for reduction rather than extermination of tsetse. They are not tent right! that much more thought should be given to *Glossina* as a vector of trypanosomiasis.

The most original part of the paper discusses the "broad ecological approach which seeks so to modify the whole environment that it becomes inimical to the continuance" of trypanosomiasis. The authors focus attention not on individual organisms but on populations of cattle, men and fly and on their inter relationships. They suggest that wars and European penetration introduced new problems and diseases (rinderpest, smallpox). Old ways of using land and old pastoral customs were replaced by groundnuts, lorries, main roads and freedom of movement. This produced a vast biological disequilibrium. (There is left an impression that this part of the picture is not yet quite in focus. The authors have put together many fragments of evidence supporting their view and with further work it may become more concrete and precise. Certainly they have performed a service in calling attention to the need to go more time and study to the African habitats as an integral part of the epidemiology.)

P. A. B. Shaw

GEIGY R. Elevage de *Glossina palpalis* (Rearing of *Glossina palpalis*). *Acta Tropica*, Basel 1948 v. 3 No. 3 201-18 8 figs.

The paper carries on the story of the cultivated strain of *Glossina palpalis* which has been maintained for some time in Switzerland. The paper describes and figures the author's methods for feeding and maintaining his large culture of tsetse. The system is evidently remarkably efficient and appears to be capable of indefinite extension as the number of flies increases. It is labor saving for one laboratory assistant can look after a couple of thousand flies, giving three to four hours to it every day. In that time he can feed them and collect pupae and dead flies.

Several distinct cultures have been maintained. One of them contained ninety-eight females and a number of males, which were brought from the Congo in October, 1945, a few pupae were added to it soon afterwards. The numbers have twice increased up to fourteen to fifteen hundred, but in the hot summer of Switzerland they tend to fall, deaths occurring when the temperature in the cage passes 30°C for considerable periods. Similar figures have been obtained with the other strains.

The notes on biology repeat to a considerable extent what the author has already published P A Buxton

LAPEYSSONIE, T C L. Trypanosomiose humaine [Human Trypanosomiasis] *Bull Méd de l'Afrique Occidentale Française* 1947, v 4, No 3, 261-73

This is a general account, emanating from the *Centre d'Etude des Trypanosomoses Africaines*, on the subject of human trypanosomiasis, with particular reference to diagnosis and treatment under field conditions. It seems to be intended mainly as an introduction for new medical officers, and should serve sufficiently well for this purpose, though there are several misleading oversimplifications or statements which are of at least a controversial nature, as, for example, the following—It is stated that the pathogenic agent is essentially *T. gambiense* in West and Central Africa and *T. rhodesiense* in East Africa, it is claimed that cross-immunity tests are necessary in order to distinguish between these two species [implying the fallacious corollary that such tests can be depended upon to establish the identity of different strains of the same species], a possible reservoir in game and cattle is held to have been disproved for both the main forms of human trypanosomiasis.

There is little that is new in the more detailed sections on diagnosis and treatment, which evidently refer only to *gambiense* sleeping sickness. Tartar emetic has been abandoned, and atoxyl and orsanine are gradually dropping out. The view held generally by French field workers is repeated that tryparsamide is, in words quoted from VAUCEL, the least effective of trypanocides ("le moins bon des trypanocides"), that is, it does not destroy parasites in the lymphatico-blood system and should therefore be used *only* in second stage cases, or, if used in the first stage, it should always be preceded by atoxyl, suramin or pentamidine. Cases which do not respond to tryparsamide in the second stage are given a course of 20 injections, with an interval of 4 days between each injection, of 4 mgm suramin and 16 mgm tryparsamide per kilo body weight, the two compounds being administered simultaneously in the same syringe.

Measures directed against the tsetse fly are mentioned with faint enthusiasm, and in the briefest possible way in hardly more than a single page.

E M Lourie

BRUN-BUISSON, P, DIALLO, J, PIRIOU, L & CAILLE, J. Premiers essais de chimio-prophylaxie de la trypanosomiose humaine en Afrique Occidentale par la pentamidine [The First Trials of Pentamidine as a Prophylactic Agent against Sleeping Sickness in French West Africa] *Bull Méd de l'Afrique Occidentale Française* 1947, v 4, No 3, 257-9

These trials were carried out at the end of 1946 and in January 1947, in the sub-divisions of Gueckédou, French Guinea, and Sedhiou, Casamance.

In Gueckédou the trials involved 5 villages in 4 cantons where the Indices of New Cases were 1.4, 1.5, 1.9 and 3.4 per cent, respectively, and in Casamance in 2 villages in cantons where the Indices were 0.60 and 2.73 per cent, respectively. The inhabitants of these villages were divided into 2 groups, approximately equal in number and in sex- and age-distributions. The first

group received prophylactic treatment and the second served a control. Half the treated group received pentamidine in a single intramuscular injection of 3 mgm. per kilo the remainder receiving a single injection of 6 mgm. per kilo (with a ceiling dose of 300 mgm.)

About 6 months later no infections were discovered among the 100th treated persons while there were 19 among the 80th controls (2.1 per cent. infection rate).

This is described by the authors as the only method of protection applicable to forest regions and the intention is to extend it in the near future to the most heavily infected cantons in the sub-divisions of Sédou (Cassamance) in Guinée and VZérékoré (Guinea) and, if possible, to selected areas of the Ivory Coast.

E. M. Lewis

GOVIALES VICENTE D. Estado actual de la tripanosomiasis humana en la zona sanitaria de San Carlos (Fernando Poo). [Present Incidence of Human Trypanosomiasis in San Carlos, Fernando Pó.] *Med. Colonial Madrid* 1948, Vol. 1 v. 12, No. 5 283-323 9 figs. 1 map & 2 graphs. [55 ref.]

The trypanosome responsible for human sleeping sickness in San Carlos is *T. gambiense* and the vector *G. palpalis* for all those specimens captured during the period 1943-48 were of this species. In this district this trypanosome is pathogenic also for the guinea pig, the white rat, the dog and the pig particularly the dog and next to this the white rat. Wild animals, e.g. the antelope are believed to play a very small part as reservoir hosts. The author describes the clinical symptoms in man in considerable detail but the account contains nothing new. The Health Organization aims at a three-monthly examination of all the population. Treatment by Bayer 205 and trypanamide combined has given the best results. In early cases Bayer 1.2 gm. for each injection (consecutively for the first 3 days and thereafter at intervals of 2 or 3 days) to a total of 8-10 gm. according to the weight of the patient then, after an interval of 8-10 days trypanamide 1.2 gm. weekly to a total dosage of 20-24 gm. for an adult of 60 kgm. If the patient presents himself with nervous symptoms and there are definite changes in the cerebrospinal fluid trypanamide is given first then the Bayer and a return to the trypanamide until the fluid is normal careful look-out being made for toxic symptoms hepatitis, optic neuritis etc. The reduction of cases is shown by the figures for each year from 1933 to 1945. The following has been compiled from figures given in the text and shows a reduction from 15.4 to 0.4 per cent. of the population.

Year	1933	1934	1935	1936	1937	1938	1939
Population	4,851	5,747	6,552	6,250	6,500	4,918	5,215

PELLEGRINO, J. Distribuição e índice de infecção dos triatomídeos transmissores da doença de Chagas no sudoeste de Minas Gerais. [Distribution and Infectivity Index of Triatomidae in South-west Minas Gerais.] *Rev. Brasileira Med.* Rio de Janeiro. 1949 Aug. 3 No. 8 555-64 3 figs. (maps) & 2 graphs. English summary.

Perusal of the spot-map which accompanies this article will demonstrate more clearly than pages of description the distribution of the eight species of

Triatomidae which are present in North-west Minas Gerais. The species are *Panstrongylus dasy*, *P. megistus*, *P. geniculatus*, *Psammolestes coreodes*, *Triatoma infestans*, *T. sordida*, *T. rubrofasciata* and a species undetermined, and the distribution is marked in over 40 municipalities and districts. The different localities in the various municipalities and the species found in each are also presented in a table. The numbers of insects examined—males, females, larvae and nymphs—of each species and the numbers found infected by *T. cruzi* were also determined. Three species only were found to be infected, viz *T. infestans*, *T. sordida* and *P. megistus*. Of 4,984 *T. infestans* examined, 1,365 (27.4 per cent) were infected, the numbers examined were distributed as follows, the numbers found infected being in brackets: males 1,894 (620), females 1,503 (499), larvae 166 (12), nymphs 1,421 (234). Of 233 *P. megistus* 11 were positive (4.7 per cent), 42 (3) males, 77 (3) females, 12 (0) larvae and 102 (5) nymphs. Of 51 *T. sordida*, 12 were positive: males 16 (1), females 30 (9), no larvae, nymphs 5 (2).

The author sums up by saying that among 48 municipalities studied Triatomidae were found infected in 34. Also that whereas in other parts of the State *P. megistus* and *T. sordida* predominate, in the south-west *T. infestans* is largely, in fact almost entirely, responsible for transmission of Chagas's disease.

MUNIZ, J. Do valor da reação de precipitina no diagnóstico das formas agudas e sub-agudas da "Doença de Chagas" (Trypanosomiasis americana) [The Precipitin Reaction in the Diagnosis of Chagas's Disease] *Mem Inst Oswaldo Cruz* 1947, Sept, v 45, No 3, 537-49, 1 fig & 1 graph. English summary.

The precipitin reaction has, in the author's hands, proved most valuable in the diagnosis of early cases of Chagas's disease when symptoms are slight and liable to escape notice. Other methods of diagnosis take up much time, such as examination of thin and thick films of blood, cultivation, xeno-diagnosis, inoculation, etc. By the test here described a very small quantity of serum is needed, only 0.1 cc for the test and the same for a control, and the result can be read off in a couple of minutes in some instances. So far, the author has obtained positive results in every one of 32 cases. The test is of little value in chronic cases: in more than 200 such only 18 per cent gave positive results to the precipitin reaction. For chronic cases, therefore, other methods are better.

The material for the test is prepared as follows —

0.5 cc of a culture of the trypanosomes, 6-8 days old, is removed from the medium, washed in physiological saline and centrifuged. 1-1.5 cc formamide (Kahlbaum) is added and, after shaking, the suspension is heated to 150° in a glycerin bath for 10-15 minutes. It is then cooled and 5 cc of acid alcohol added. This is repeatedly shaken for 15-20 minutes and centrifuged. The supernatant fluid is placed in a fresh centrifuge tube and 10 cc of pure acetone added. After rapid shaking it is put aside for 10-15 minutes and again centrifuged. The fluid is discarded and the residue placed in a vacuum chamber to get rid of the moisture. To the precipitate are added 2-3 cc of 0.85 per cent saline.

For the test, 0.1 cc of the serum, clear and non-haemolysed, is placed in a small tube 3 mm in diameter, and the precipitinogen in the same quantity is introduced slowly down the side of the tube. In a positive case a turbid disk forms in 1-2 minutes at the junction of the fluids, but a limit of 10 minutes is interpreted as 4-plus, 10-20 minutes as 3-plus, after 30 minutes as 2-plus.

LEISHMANIASIS

LOZANO MORALES A. Aportación al estudio de la epidemiología del Kala-azar infantil. [Contribution to the Study of the Epidemiology of Infantile Kala Azar] *Rev. Sanidad e Hig. Pública* Madrid. 1948 Aug. v 46 No. 8, 781-4

In the Antimalaria Institute of Cáceres, Spain, the author has seen 38 cases of infantile kala azar (one table totals 39) in the years 1941-45—one was diagnosed by the finding of leishmanias in the peripheral blood, all the others by splenic or sternal puncture. The numbers in consecutive years are given as 7 11 9 5 and 7 respectively. Of the 38 there were 9 under 1 month old, 23 between 1 and 3 years, 3 between 4 and 6 years, 3 more between 7 and 10 years. These last were all girls, but sex plays little if any part as regards incidence of the total, 17 were boys, 21 were girls, and up to 6 years the figures were 17 and 18 respectively. Practically all the patients lived in or came from rural districts.

11 Harold Scott

GÓMEZ J. DE CISNEROS J. M. Contribución al conocimiento del Kala-azar en la provincia de Murcia. [Kala Azar in the Province of Murcia, Spain.] *Rev. Sanidad e Hig. Pública* Madrid. 1948 Oct. v 50 No. 10 1017-24 2 figs. on 1 pl. [37 refs.]

This contribution is mostly in general terms telling of the findings in smears made from the sternal marrow of the biochemical test of Chopra and Gupta, the formal-gel of Napier, etc. The authors then state that both the visceral and cutaneous forms of leishmaniasis occur in the Province—they have seen 30 cases in children and one in an adult of 73 years, all proved by sternal puncture and 20 cases of oriental sore. They place no great reliance on the biochemical tests except as pointers calling for confirmation by examination of the sternal marrow.

CHAND A. GUPTA D. C. & CHITTANI P. N. Indigenous Kala-Azar in the Punjab. *India Med Gaz.* 1948 June. 83 No. 6 291-3

Two cases of kala-azar have been reported—one of which got infected in Lahore. Evidence in favour of possible indigenous infection has been produced."

BUSTAMANTE, M E Epidemiología de la leishmaniasis en América [Epidemiology of Leishmaniasis in the Americas] *Bol Oficina Sanitaria Panamericana* 1948, July, v 27, No 7, 611-18 [18 refs] English summary

An article of much interest and a plea for more systematic study of leishmaniasis and interchange of information. Speaking generally, the parts of America in which leishmaniasis is found are wooded, moist and warm, except parts of Peru in which espundia is common. Visceral leishmaniasis is most frequent in the equatorial wooded parts of Brazil, Bolivia, Paraguay and the Argentine. Barretto divides the *Phlebotomus* species into domestic, associated with man and domestic animals housed close by, as *P. argentipes* [an Indian species], semi-domestic, living outside the dwellings but feeding on the blood of man and domestic animals, as *P. intermedius* and *P. fischeri*, and sylvan, living in forested areas and only accidentally associated with man and domestic animals, as *P. noguchii* and *P. ayrozoai*. Of those named, the first three only are known to be natural vectors. [It appears that *P. fischeri* was infected experimentally with *L. braziliensis* once in 1941.]

Of 1,506 persons examined, mostly collectors of chicle gum, 11 per cent altogether were infected, 17 per cent were male adults, 2 per cent women and 0.7 per cent children. *L. braziliensis* was the infecting parasite. In 61 per cent the ears were the sites of lesions, in 15 per cent the arms. Wood cutters in Yucatan are much affected. A long list is given showing the nine possible vectors and the places where they have been reported and the proposal is put forward "That the Pan American Sanitary Bureau be requested to act as a center of information and coordination between the institutions and the investigators interested in the study of leishmaniasis, with the purpose in view of aiding in the formulation of a methodical joint investigation program in the Western Hemisphere."

SANCHIS BAIARRI, V & MARCO AHUIR, R Sobre el sero-diagnostico del kala-azar con el antígeno metilico tuberculoso [Sero-diagnosis of Kala Azar with Tuberculous Methyllic Antigen] *Med Colonial* Madrid. 1948, Nov 1, v 12, No 5, 279-82

Deviation of complement with the Witebsky-Klingenstein tuberculous antigen has been recorded in cases of kala azar. Not having this antigen at hand, the authors used the methyllic antigen of Boquet and Nègre. With this, 18 out of 20 patients, diagnosed by splenic puncture as suffering from kala azar, gave a strong positive, fixing 6-18 haemolytic units, the other two giving a weak positive, 1-3 units. None of a control batch gave the reaction. In the present paper eight cases are noted briefly. One patient, who had been clinically cured 5 months before, still gave a positive reaction (5 units). Subsequent examinations should show whether this patient has really been cured or is only exhibiting temporary improvement, another, recorded as cured a year before, gave a weak positive (1 unit). One other, with typical blood condition, gave a positive (3 units) although no leishmania were seen on spleen or sternal puncture. Another, suffering from acute myeloblastic leukaemic leukaemia, in whom no leishmania were found, gave a negative to the complement fixation test.

H Harold Scott

TRIACÃO, C Subsídios para o esclarecimento de alguns aspectos dos problemas do kala-azar [Aids to the Elucidation of certain Problems in Kala Azar] 127 pp., 1 fig [Numerous refs] 1948 Lisbon

In his preface to this work the author disarms criticism by stating that he deals with only a few of the problems of kala azar and that the form in adults

only is considered. [But later in the section dealing with the spleen, details of the different cells are given in 13 cases 3 only of which are in adults and the remainder infants.]

A few words will explain the general plan of the work which has necessitated a wide study of the literature of the subject. One new process has been removed and this will be referred to later. The author takes up various points in turn and gives in each case the development of knowledge with the passage of time and the records of research each chapter or section ending with a fairly full bibliography. He then, in the appropriate sections, notes how his own observations agree with those stated. After an opening chapter on Portuguese literature on kala azar sections on the pathogeny and morbid anatomy as to blood-picture, the bone marrow and spleen smears and the different cells of blood, marrow and spleen the anaemia and the chemical changes in the liver the flocculation reactions used in diagnosis and lastly cultivation of *L. donovani* are devoted to each of these in turn.

The only new matter recorded is another gel reaction which, like many discoveries of note, was of the nature of an accidental occurrence. The author was estimating the iron in the serum of two kala azar patients by Schales' method the first stage of which consists in treating the serum with 0.3N HCl 2 parts serum to 1 part acid for one hour. When after this lapse of time it was about to pass on to the next stage to his surprise he found the mixture "gelled". Repeating the process he found that this gelification occurred in 15 minutes. With the sera of other kala azar patients one clinically cured and giving Napier ++ did not gel with the HCl at the end of an hour but a much more viscid than normally. Another who was under treatment gave a Napier 3-plus and an HCl gel in 24 hours. Three others, after their treatment had ceased, gave a Napier 1-plus but only increased viscosity no gel with the HCl.

The author therefore standardized his results thus. Those giving a gel within an hour 2-plus, those within 24 hours 1-plus. Those giving increased viscosity but not a gel ±. In a table he compares the results in 18 cases 9 untreated, 4 under treatment 1 inadequately treated (presumably having left off treatment as this is listed separately from the under treatment patients) and 4 cured, by the formaldehyde method of Napier and his own HCl method. One under treatment one untreated, and one clinically cured were negative to both. One untreated was negative with HCl but 2-plus with formalol but ± with HCl. In general, the others all showed a reaction less marked than with Napier's method. The author concludes by saying in regard specimens that having carried out Schales's method of estimating Fe in the serum in patients suffering from various diseases he has observed 2-plus only in cases of multiple myeloma (in which the formalol gel gives 3-plus) otherwise having made thousand of serum-iron estimations by this method.

Up to the present we have never observed results similar to those in kala azar. The reaction we note as ± is not so strictly specific. We have observed it in cases of hepatic cirrhosis.

FEVERS OF THE TYPHUS GROUP

BARNES, A. C. ***Proteus OX19* Agglutination in Pregnancy** *Amer J Clin Path* 1948 Aug, v 18, No 8, 635-6

GRATCH [this *Bulletin*, 1944, v 41, 197] reported that *Proteus OX 19* was agglutinated by the sera of all of 505 pregnant women examined. This finding was of interest in relation to the interpretation of the Weil-Felix test and as a possible basis for a test for pregnancy. The present paper gives details of results obtained with the sera of 402 women, of whom 207 were pregnant. A commercial *OX 19* antigen was used, tests being made by a slide technique. A higher percentage of the sera from pregnant women (73.9 per cent) gave a positive result than those from non-pregnant women (41.6 per cent) at a titre of 1/20 or over. It is considered that the finding is not sufficiently constant to serve as an aid to pregnancy diagnosis, but that it may be important in relation to the diagnosis of rickettsial disease.

[The detailed figures now recorded are in close accord with those of NELSON and CRICKSHANK (this *Bulletin*, 1945, v 42, 363) who found agglutinins to *Proteus OX 19* with greater frequency in the sera of pregnant women than in normal sera, but not with such constancy or to such high titres as had been reported by GRATCH.]

J. C. Crickshank

LODENHAMPER, H. Beitrag zu Erfahrungen mit der Weil-Felix-Reaktion [Studies of the Weil-Felix Reaction] *Ztschr f Immunitätsf u Exper Therap* 1943, Nov 18, v 104, No 1, 1-18 [27 refs]

The author gives his own experience of the Weil-Felix test and a critical review of the recent German literature of the subject.

An interesting comparison is made of the titres observed in a series of tests carried out simultaneously on sera of patients suffering from fevers other than typhus with two strains of *Proteus OX19* supplied to the German Field Laboratories during the Second World War. The findings are shown in the table—

Titres		0	1-50	1-100	1-200	1-400	Total
Strain	Do	464	71	40	2	0	577
Strain	No	323	115	99	36	4	577

In tests carried out on typhus patients the titres were usually so high that practical difficulties rarely arose even when the titres observed were widely different.

Typhus patient who had been vaccinated against the disease a high titre at low titres or not at all but among non-vaccinated patients the reaction is regarded as diagnostic in almost 100 per cent of the cases.

Extraordinarily high titres were sometimes observed such as one of 1:160,000 in a serum whose reading was made after 24 hours and one in which the titre reached 1:409,600 after two hours.

The author like most other observers of the reaction makes little reference to the diagnostic significance of the low but rising titres observed during the early stages of the illness.

John H. D. Meyer

TRIFFTERER, Theresia. Zusammenhang zwischen der Weil-Felix-Reaktion und der Präzipitation des O-Antigens des *Proteus* *bazillus* \ 19. The Correlation between the Weil-Felix Reaction and the Precipitation of the O-Antigen of *Proteus* \ 19. *Ztschr. f. Immun. u. Exper. Ther.* 1943 Vol. 18 \ 104 No. 1 41-50 [68 ref.]

The first part of this paper consists of a very useful documented review of the literature dealing with the antigenic structure of *Proteus* \ 19 and other organisms. The bibliography contains 63 references.

The second part contains the results of a series of comparative tests in which typhus and other sera were submitted to the Weil-Felix reaction and to a precipitation reaction in which the antigen was a solution of a glucolipid extracted by BOULE from *Proteus* \ 19. The name glucolipid was given by BOULE *et al* [see *Bulletin of Hygiene* 1938, v. 11 589 1938 v. 13, 842 1939 v. 14 344] to water-soluble substances contained in various Gram-negative bacteria, including *Proteus* \ and consisting of the polymaccharide species of each organism combined with phosphates. The glucolipids are regarded as the O-antigens of the organisms.

In conformity with the findings of UICHA *et al* [ibid. 1938, v. 13 746] the author found that a fairly uniform correlation existed between the Weil-Felix titres of the sera and the maximum dilution of the glucolipid which produced precipitation when added to the sera.

Sera with Weil-Felix titres of less than 1:200 usually gave negative reactions with the precipitation test even with the strongest solution which was 1:2,500. Titres of 1:400 corresponded roughly with precipitation reactions with solutions of 1:25,000 and titres of 1:800 with reactions with solutions of 1:50,000.

The glucolipid solution was highly toxic to mice when given intracranially when previously mixed with immune sera having high Weil-Felix titres the toxic action was inhibited.

John H. D. Meyer

MORONES S. Tratamiento del tabardillo con el A.B.V. Treatment of Tabardillo with *Para*-aminobenzoic Acid. *Cien. Med. y Quim.* 1943 Apr. 30 74 Nos. 12, 73-7

In a series of controlled trials the author found that *para*-aminobenzoic acid given in the usual doses caused no significant benefit to patients suffering from tabardillo whose treatment was started after the appearance of the rash. The average day of the disease on which the first dose was given was 14.1 but have been the eighth. A definition given of the name tabardillo previously the disease was house-borne typhus. The failure of the drug when given late in the course of the illness is not surprising. MORONES *et al*. had a similar experience [see this *Bulletin* 1943 4, 201] John H. D. Meyer

PAYNE, E H, SHARP, E A & KNUDT, J A Treatment of Epidemic Typhus with Chloromycetin *Trans Roy Soc Trop Med & Hyg* 1948, Sept, v 42, No 2, 163-70, 1 plan & 2 figs on 1 pl

The authors have obtained remarkably successful results in the treatment of 22 cases of louse borne typhus with the new antibiotic, chloromycetin [see this *Bulletin*, 1948, v 45, 779]

The cases were seen at Puerto Acosta in the province of Camacho, Bolivia. Four of the patients "presented signs and symptoms of probable death," and five others "gave evidence of certain death," yet all made a rapid recovery. The day of the disease on which treatment was started is mentioned in only three of the cases, in which it ranged from the 6th to the 12th day.

In nine of the cases the temperature became normal within 24 hours, and in none of the others did the fever last for more than 54 hours after the first dose was given. The pulse responded with equal promptitude, and the patients usually "entered convalescence" within three days.

The dosage adopted towards the end of the study was 1.5 gm given by the mouth once daily for two or three days, this system gave as good results as were obtained in earlier cases in which larger doses were given over longer periods. Oral treatment was as effective as intravenous, but the response was delayed by eight to twelve hours, probably because the tablets used were excessively compressed and took several hours to disintegrate.

Intravenous treatment was by a solution containing 1.0 gm in each phial of 10 cc, the solvent being propylene glycol. The usual dose was 0.2 gm, given very slowly, and four or five such doses were given daily, usually in addition to oral treatment. The total amount of chloromycetin given to adult patients was usually 4.0 to 5.0 gm during the early part of the study, one patient, exceptionally, received 8.8 gm.

No toxic reactions were observed, on the contrary the authors state that "the rapid beneficial effect on the heart action suggests that chloromycetin has the additional virtue of being a myocardial tonic."

Among 50 untreated cases occurring in the same epidemic, there were 14 deaths, but although no details are given to show that these cases were strictly comparable the evidence produced by the authors amounts almost to proof of the great efficacy of the drug.

John W D Megaw

MARIANI, G Le piu recenti osservazioni in Italia sull' impiego del vaccino anti-dermotifico [The Most Recent Observations in Italy on the Use of Typhus Vaccine] *Ann d Igiene* 1948, Jan-Feb, v 58, No 1, 43-5

GRASSI-BERTAZZI, C Reperto di elementi rickettsioidi negli endoteli polmonari di ratti portatori di virus murino dermatofoso [Presence of Rickettsial Elements in the Lungs of Rats Infected with Murine Typhus] *Acta Med Italica* 1948, Sept, v 3, No 9, 228-31, 4 figs [20 refs]

The English summary appended to the paper is as follows —

"The author, during systematic research in 17 rats of the town of Catama, could demonstrate the existence of the virus of typhus, through inoculation in guinea pigs, notwithstanding the actual absence of signs of disease. In 5 of these 6 cases he could put in evidence, in the lungs, a high number of rickettsioid elements."

POMALES LEBRON A. ARROYA G. MORALES OTTERO, P. & LOTTING L.
 Les réactions de fixation du complément et de Weil Felix dans l'éryth
 typhus des rats sauvages à San-Juan et Santurce (Puerto-Rico). The
 Complement Fixation and Weil-Felix Reactions in the Study of Typhs
 among Wild Rats in San-Juan and Santurce (Puerto Rico). Arch. du
 Pasteur de la Martinique 1948 Jan., v. 1 No. 1 91-8

Between 7 December 1944 and 22 June 1945 the sera of 413 wild rats caught in San-Juan and Santurce were tested by the complement fixation reaction (epidemic typhus antigen) and sera of 251 of these rats were tested also by the Weil-Felix reaction. With the former test 54 per cent. of the rats gave positive reactions at unstated titres with the latter test 4 per cent. reacted at titres ranging from 1-25 to 1:1,600.

During the three months January to March 1945 there were 28 cases of murine typhus in the two towns whose combined population was 70,000 and during the three months April to June of the same year there were 7 cases, but the percentage of positive fixation reactions among rats was about the same in the two periods. Among full-grown rats (100-200 gm.) 6 per cent. of fixation reactions was 70 among the small young rats (25-50 gm.) the percentage was 42.

Among the 251 rats subjected to both tests 139 gave positive fixation reaction and 42 of these reacted also with the Weil-Felix test of the 117 rats that did not react with the fixation test 19 gave positive Weil-Felix reactions.

COCHRAN H. L. Successful Methods of trapping Trombiculids (Acarina) with Notes on rearing *T. deliensis* Walch. Bull. Entom. Res. 1945 1st v. 39 Pt. 2, 281-86 5 figs.

Some methods of trapping Trombiculid mites are described which are based on their reactions to light and warmth and their tendency to climb upwards. The details of construction are illustrated by drawings.

A field mite-trap for collecting unengorged larvae consists of a Petri dish containing a filter paper cone which is placed on the ground and covered with a black metal tray three feet square and three inches high. This cover has a two-inch circular hole in the centre which should be placed immediately above the paper cone. Specially shaped wooden battens screwed to the cover give it a rise from sides to middle of half an inch. A glass specimen tube 1½ inches in diameter is fixed, by means of a grooved rubber ring, half way inside a two-inch diameter tube. These tubes are put mouths downwards into the hole in the cover in such a way that the inner tube rests on the paper cone. This is the only source of light beneath the cover. Larval mites within the square yard enclosed by the cover go towards the light, climb the Petri dish and the cone and are trapped in either one tube or the other. The trap is left in position for four and a half to five hours.

Another method for collecting larvae is by using bait animals. The guinea pig and the golden hamster were found to be the most suitable animals. Wire cages, each containing two animals, are placed on the earth to form a circle leaving a space equal to the width of one cage between the cages. The cages are moved one space every hour until a complete circuit has been made. Before exposure the animal should be clipped short around the genital perineum and ears to facilitate rapid examination for larval mites.

A laboratory light trap was originally used in Assam for collecting replete larvae of *Trombicula deliensis* from laboratory rats. It was also used in England for recovering engorged larvae of *T. autumnalis* from the bait animals. The light trap consists of a square box big enough to hold two guinea pigs, one on each

the box is closed by a wire mesh door, fixed at the other end is a black paper funnel twelve inches long, tapering to an aperture one inch in diameter. A filter paper tongue is attached to the aperture and leads to a Petri dish containing water. When in use the box is raised at one end so that the larvae walk up a slight gradient towards the opening in the funnel, opposite which is a 25- or 40-watt lamp, nine inches away. Larvae have appeared on the filter paper tongue within three minutes of the funnel having been placed in position. For some purposes a specimen tube can be substituted for the filter paper tongue.

"Flagging" is a method of collecting larvae in the field, by trailing a coarse cloth over the ground, but it is considered unsuitable for survey work except in the absence of a field mite trap. This method probably collects only a small proportion of the larvae and the task of removing them from the cloth is very tedious, though the light trap could be used for this purpose.

Flotation is employed for collecting adult mites from soil. A soil sample is sprinkled into a sink containing warm water three inches deep. The soil is stirred twice for a minute and the adult mites are then picked off the water surface. After five minutes no more adults appear. This method is not suitable for recovering large numbers of nymphs as they are more fragile than the adults and more easily wetted. Field observations on the movements of adult *Trombicula autumnalis* in moist soil showed that they rise towards the surface when the air temperature is high and go deeper when the temperature is low. They also go deeper when the soil is dry and rise after rain.

For the rearing of nymphs for systematic purposes, engorged larvae are put into a cloth-bottomed metal cell $\frac{1}{2}$ to $\frac{3}{4}$ inch in diameter and an eighth of an inch deep, a coverslip is sealed with wax on to the top of the cell. The cell is then kept in a moist atmosphere in a Petri dish. When larvae show signs of undergoing metamorphosis the cell is lightly flooded, the nymphophanes which float off the cloth are picked out and placed singly in other cells from which the nymphs and their larval pelts are obtained and mounted on slides for microscopical examination in polyvinyl alcohol.

WILLCOX, P H A Mite Typhus Fever in Assam and Burma, 1944-1946.
Trans Roy Soc Trop Med & Hyg 1948, Sept, v 42, No 2, 171-89
[34 refs]

Of the 493 cases studied, all but 17 occurred at Imphal and Palel during the six months, July to December, 1944, so that to all intents and purposes the description of the clinical findings refers to this outbreak.

The case fatality rate was 8.3 per cent, this was not high, considering that the patients had been greatly debilitated by wartime hardships in highly malarious areas and had usually been admitted to hospital after a trying journey lasting two days.

The author was struck by the close resemblance of the clinical and pathological features to those of louse-borne typhus.

Headache occurred in every case, there were mental changes in 95 per cent of the cases, enlarged glands in 90 per cent, chest signs in 75 per cent, and conjunctival injection in 68 per cent. A rash was seen in 77 per cent of the European, in 31 per cent of the Indian, and in 27 per cent of the East-African, patients. An eschar was seen in 20 per cent of the cases. The average duration of the fever was 17.2 days.

Numerous references are made to observations on wartime mite typhus by other authors, one of these is misleading—it seems to suggest that the outbreak at Ranchi in 1943 was mite-borne, whereas it almost certainly was tick-borne and is so described by BOWEN [see this *Bulletin*, 1948, v 45, 63].

VALLEJO-FREIRE, A. Febre maculosa no México. Cultivo de Rickettsia [Spotted Fever in Mexico. Culture of Rickettsia.] *Mem. Inst. Bacteriol.* 1947 v 20 1-11 8 figs. [23 refs.] English summary

Both versions of the title of this paper are copied from the index to the journal in which it appears. The spotted fever referred to is the form of the borne typhus indistinguishable from Rocky Mountain spotted fever.

A detailed description illustrated by six photographs is given of the cultivation of the rickettsiae by Cox's method. The technique and apparatus employed are clearly described. An Oswald oxy-acetylene blow pipe (for W 29 bico No 2) is used for making apertures in the shell for the asexual introduction of the infecting material into the yolk sac, and for cutting off a cap of the shell preparatory to the extraction of the incubated sac.

An interesting point is that the author has never been able to detect the presence of rickettsiae inside the nuclei of the cells in stained preparations, though the intranuclear localization of the organisms has been regarded as the chief point of difference between *Dermacentorinus* [Rickettsia] nuclei and the rickettsiae of the other fevers of the typhus group.

The original inoculum from which the cultures were prepared was obtained from blood, brain substance and tunica vaginalis scrapings of guinea-pigs infected with a strain of rickettsiae isolated by BERTAMANTE and VARELA from a patient in Mexico. The number of rickettsiae seen in stained smears of vaginalis scrapings became much greater after the fifth passage. Thus the seen in other spotted fever strains.

VALLEJO-FREIRE, A. Transmisão do vírus da febre maculosa mexicana por *Amblyomma striatum* Koch, 1844 [Transmission of Rickettsia of Mexican Spotted Fever by *Amblyomma striatum* Koch, 1844.] *Mem. Inst. Bacteriol.* 1947 v 20 107-12. English summary (5 lines)

The author has succeeded on one occasion in bringing about the experimental transmission of Mexican spotted fever rickettsiae from guinea-pig to guinea-pig by the bite of *Amblyomma striatum*. It has also demonstrated the presence of infection in the eggs of an experimentally infected specimen of the same species of tick.

The strain employed was the one used in the experiments described in the preceding paper.

LOCKE, R. F. & HEALING, R. J. The Veterinary Public Health Significance of Q fever. *J. Amer. Vet. Med. Ass.* 1948 Nov. 113 No. 440 444-7. 14 refs.

GUTSCHER, V. & NUTER, H. Ueber eine Queenslandfever Epidemie in Bremgarten (k. t. Aargau) [An Outbreak of Q Fever in Bremgarten (Aargau Canton, Switzerland)] *Schweiz. med. Woch.* 1948 Oct. 30 74, No. 41 1064-6. 2 figs.

A retrospective diagnosis of Q fever was made in the case of a worker in a furniture factory who had been attacked on 6th April, 1948, by an illness diagnosed as bronchopneumonia. His complement-fixation reaction for Q fever was positive at a titre of 1-840. On enquiry it was found that 59 of the 100 persons employed at the factory had been attacked by an influenza-like illness between 14th March and 23rd April. Most of the 34 former patients who were investigated gave histories of illness suggestive of Q fever and positive complement fixation reactions. None of the unaffected workers who were examined gave positive reactions.

An epidemiological investigation failed to reveal the source of the infection.

PARKER, R R, BELL, E J & LACKMAN, D B **Experimental Studies of Q Fever in Cattle I Observations on Four Heifers and Two Milk Cows**
Amer J Hyg 1948, Sept, v 48, No 2, 191-206

The purpose of these studies was to obtain evidence with regard to the mode of transmission of Q fever. Two lactating cows were successfully infected. One cow was inoculated with a yolk-sac suspension of *Coxsella* [*Rickettsia burnetii*] which was introduced into three of the quarters of the udder, one dose was given via the milk duct, another was injected into the body of the mammary gland of another quarter, and the third was injected subcutaneously over the gland of one of the two remaining quarters. Milk from the quarter inoculated via the milk duct was repeatedly found infected up to the 17th day, and milk from the quarter inoculated via the body of the gland remained infected up to the 40th day. Milk from the other two quarters was not infected.

Blood of this cow gave a positive complement-fixation reaction from the 5th day and the titre rose to 1-256 by the 7th day. The cow showed no signs of illness at any time.

The other cow was inoculated via the milk duct of one quarter with a yolk-sac suspension containing five million infectious doses for a guineapig, the milk of the inoculated quarter remained infected up to the 40th day, milk from the adjacent two quarters was not infected. The cow showed no signs of illness, and repeated inoculation of guineapigs with her nasal washings, urine and faeces gave negative results.

Four heifers aged seven to ten months were inoculated with infected material in the following ways: (1) spleen suspension of an infected guineapig was sprayed intranasally into one; (2) infected yolk-sac suspension was injected intravenously into another; (3) bran contaminated with infected yolk-sac material was given orally to the third animal, and (4) a suspension of infected guineapig spleen was introduced into the vagina of the fourth. Repeated inoculation of guineapigs with blood, nasal washings, urine, and faeces gave negative results, except that the urine of the animal inoculated through the vagina was infective on the 5th and 9th days, probably by contact with the original infected material. None of the heifers gave a positive complement-fixation reaction at any time.

Full details are given of the technique employed by the authors. The findings are regarded as suggesting that cows may become infected through the milk ducts, either during milking or through contact with bedding contaminated by infected urine. The need for further study of the problem is emphasized.

John W D Megaw

BARTONELLOSIS

RICKETTS, W E **Bartonella Bacilliformis Anaemia (Oroya Fever) A Study of Thirty Cases** *Blood* 1948, Sept, v 3, No 9, 1025-49, 12 figs [50 refs]

[A report of a careful study with results of much informative value] The author discusses the findings in 30 cases of anaemia with the presence of *Bartonella bacilliformis* in the erythrocytes. Details of repeated examinations of the blood of uncomplicated cases of bartonella anaemia are given in a table and records of six patients, illustrating different accompanying conditions, in one a reduction of red cells to nearly half a million per cmm, with intensive regeneration and exceptional macrocytosis; in another, early death on the 10th day with similar reduction of red cells, nearly all parasitized by *Bartonella*; a third died from a complicating thrombocytopenic purpura, a fourth from

the same although the parasites were disappearing from the corpuscles. In stage, when the organism is disappearing has been called the "critical stage" the bartonellae change from the bacillary to the coccoid form, the parasitised cells are fewer as are the numbers per cell the erythrocyte count goes, reticulocytes increase macrocytes decrease there is lymphocytosis and reappearance of monocytes and eosinophiles and a shift of the polymorphonuclear series to the right. In short convalescence seems to be setting in, but this may be deceptive complications arise and a fatal issue may occur due to intercurrent *Salmonella* infection from the intestinal tract with a general lowered body resistance.

To sum up *Bartonella* anaemia occurs in the invasive stage of the disease and not during the course of it the later forms which are seen in the pre-eruptive and eruptive stages are different morphologically and clinically and are due to haemorrhages intercurrent infections thrombocytopenia purpura and other causes. The anaemia is macrocytic in type often hypochromic with young granulocytes reticulocytosis even to 50 per cent. erythroblastosis and polychromatophilia—in short marked signs of blood formation. The polymorphonuclears show a shift to the left, with myeloblasts myelocytes and metamyelocytes present.

The prognosis is very grave of the 30 cases observed, 22 ended fatally. Fifteen suffered with intercurrent infection and 11 of these died, as did three of 15 who had no such infections. As regards treatment, some authorities have maintained that blood transfusion is dangerous because of the possible invasion of the new cells by the bartonella, but in practice patients may be greatly benefited by such treatment. Incidentally (though it is probably too late for remedy now) the author states that Oroya Fever is not an appropriate name for Bartonellosis or Carrion's disease, as *Bartonella* infection does not occur in the Peruvian city of Oroya.

YELLOW FEVER

LIXONIS, P., ROUSSEAU E. & COUTONIS C. Complément d'enquête sur la distribution de l'immunité antiamarile naturelle chez les indigènes du Congo belge. [Final Results of the Investigation of the Distribution of Natural Immunity to Yellow Fever in the Native Population of the Belgian Congo.] *Ann. Soc. Belge de Méd. Trop.* 1945, June 30 23, No 247-67 1 map

The medical laboratory at Stanleyville has been carrying out studies of immunity to yellow fever in the Belgian Congo since 1938 using the more protection test of Sawyer and Lloyd for estimating neutralizing antibodies in serum.

Most of the results obtained up to the end of 1941 chiefly in Province Orientale (including Stanleyville) have already been published in the *Bulletin* 1944 v. 41 1025 and the essential are included in the present summary.

Tests have been carried out on serum from 3 369 infants and 3 688 adults from 198 localities in 81 territories 17 districts and residences.

The regions from which only negative results were obtained are the regions at high altitudes. The results from the vast equatorial forest region indicate that the disease is of low endemicity there. The highest rates have been obtained in some parts of the lower Congo and in the north part of Ubangi and

Uele These areas are savannah interspersed in the forest galleries. However, similar high rates have not been found in similar savannah in the southern part of the Belgian Congo. There was no evidence of a recent epidemic in any region.

There were only 2 areas in which the disease had been present as recently as 1939, one 1938 and the rest in 1936 or previously, mostly before 1930.

In addition, serum from 2 of 3 chimpanzees and 1 of 3 cercopithecus monkeys had neutralizing antibodies for yellow fever virus. Serum from 3 cynocephalus monkeys, 1 cercocebus and 1 cebus were negative. *F O MacCallum*

PERLOWAGORA, A & HUGHES, T P The Complement Fixation Test in Yellow Fever Epidemiology II The Development and Loss of Complement-Fixing Antibodies in Marmosets (*Callithrix penicillata*, *C jacchus* and *Leontocebus chrysomelas*) *J Immunology* 1948, Sept, v 60, No 1, 67-75 [11 refs]

It is known that complement-fixing antibodies for viruses do not remain in the serum for long periods after convalescence. This has been shown to be true in yellow fever infection in man and rhesus monkeys. It has been shown by virus isolation and serum neutralization tests in recent years that certain species of marmosets are infected with yellow fever virus in the wild state in parts of South America, where the disease is endemic. It is difficult, however, to tell the date of the infection by the presence of neutralizing antibodies in a single sample of serum. The authors have found that complement-fixing antibodies appear between the 15th and 30th day of the infection in marmosets, reach a maximum titre in 4 to 5 weeks and then gradually disappear. One-third of the marmosets had lost their complement-fixing antibody by the third month and all but one of 26 survivors were negative by the ninth month. This test, combined with the neutralization test of the animals' serum, can thus be used to determine the approximate time of infection with yellow fever virus in marmosets in nature. *F O MacCallum*

DENGUE AND ALLIED FEVERS

YAOI, H & ARAKAWA, S Studies on Dengue (Resumé) *Japanese Med J* 1948, Feb, v 1, No 1, 4-12 [12 refs]

This paper is a summary of 12 articles by the same authors, published during the years 1943-1946. Animal experiments were carried out on much the same lines as those described in the paper below.

By using very young mice for the earlier inoculations the virus became adapted to intracerebral transmission through adult mice, young guinea-pigs, rabbits, rats, and monkeys. In the earliest passages through very young mice the incubation period ranged from "several days" to as long as 17 or even 25 days but after repeated passages a *virus fixe* was obtained which killed adult mice in four or five days.

The virus was cultivated in tissue cultures and in chick embryos, and although the lesions of the chorioallantoic membranes described by SHORTT were 'hardly observed' the latter method was found specially suitable for the maintenance of the virus in a virulent form.

CHEN JEN C. & ZIA, S. H. Study of Fixed Rabies Virus propagated in the Brain of Guinea Pig Fetus. *J Immunology* 1948, Sept. v 60 No. 1, 17-21 [16 refs.]

In view of the equivocal results obtained by previous workers in culturing rabies virus by the conventional methods, the present authors attempted to propagate a fixed rabies virus in the developing foetal brain of the guinea pig *in vitro*. In this connexion they describe the successful outcome of the experimental work and show not only that the virulence of the virus remained unchanged (10^7 to 10^9) even after 16 passages but that the culture virus vaccine possessed an immunizing potency comparable with that of an adult brain vaccine. Moreover there is an advantage in using foetal brain as vaccine instead of adult brain—an advantage corroborated by the work of KABAT WOLF and BUZZER [see *Bulletin of Hygiene* 1947 v 22, 313], who state that foetal rabbit brain failed to produce any lesion in rhesus monkeys, while adult brain when given in large doses, almost invariably produced lesions. Although the amount of material available in the guinea pig foetus is necessarily small this difficulty might be overcome by employing for vaccine production the foetuses of larger mammals such as sheep or goats.

It is noteworthy that the authors who found phenol-preserved vaccine whether made with foetal or adult tissue to be much less protective than formalized vaccine are now engaged on a detailed comparative study of the effect of phenol and formalin on the antigenicity of rabies tissue vaccine.

FREUND J., LEPTON M. M. & PISANI T. M. Immune Response to Rabies Vaccine in Water-in-Oil Emulsion. *Proc Soc Exper Biol & Med* 1948, July-Aug. v 68 No. 3 609-10

The incorporation of inactivated rabies vaccine into water-in-oil emulsion enhanced the antigenic property of the vaccine as judged by the formation of neutralizing antibodies. Allergic encephalitis did not occur unless mycobacteria were added to the emulsion.

BIGGICOMON J. R. & LAT C. Les vaccinations antirabiques à l'Institut Pasteur en 1947 (Antirabic Vaccination at the Pasteur Institute in 1947) *Ann Inst P Pasteur* 1948, A ; 73 No. 2, 163-7

A statistical summary

LUSSICH J. J. Organización de la lucha contra la rabia en la República Oriental del Uruguay (Organization of Control Measures against Rabies in Uruguay) *Bolet Oficina Sanitaria Panamericana*, 1948, July v 27 No 7 624-6

In Montevideo during the period 1927-1936 incidence of canine rabies continued on an uncomfortably high level with the result that annually more than 1,000 bitten persons had to submit to anti-rabies vaccination. In 1934 the Sanitary Authorities realizing that the steps taken up to that time had failed to reduce rabies incidence among dogs introduced the following measures of control: (1) isolation and observation of animals suspected of rabies; (2) collection of dogs found wandering in the street and destruction of those not claimed by their owners; (3) organization of a service to identify animals which had run risk of infection by rabid dogs; (4) compulsory notification of all cases of rabies or of suspected rabies among animals and destruction of all such animals; and (5) compulsory vaccination of all dogs collected off the streets and returned to their owners.

Statistics show that, between 1st October, 1934—the date on which the new measures came into force—and 31st December, 1947, of 136,008 dogs collected on the public highways, 120,946 were destroyed and 15,062 restored to their owners after having been given a single injection of Lymeo and Dor's phenolized vaccine. It is noteworthy that not a single case of rabies developed among the 15,062 dogs vaccinated. That the control measures introduced in 1934 achieved the desired result, is evidenced by the fact that in 1936 the cases of canine rabies were but 57 per cent. of those of the previous year; that in 1941 the reduction as compared with 1935 was 97·7 per cent., and that since 1944 no case of rabies has occurred among animals in the Department of Montevideo.

Moreover, in order to prevent the infection of the interior of Uruguay with rabies, which still exists near the country's frontiers, the Government on 4th July, 1946, issued a decree whereby application of the prophylactic measures in force in the Department of Montevideo was extended to the whole territory of the Republic.

PLAGUE

THOMPSON, H. V. Studies of the Behaviour of the Common Brown Rat (*Rattus norvegicus*, Berkenhout). I. Watching Marked Rats taking Plain and Poisoned Bait. 16 pp. 13 figs. [1948. London: Ministry of Agriculture and Fisheries Infestation Control.]

The author describes observations which he has made on wild brown rats (*Rattus norvegicus*) on a pig farm in England.

When it was put down regularly at one spot which was dimly illuminated by electric light. The area was watched by observers continuously for large parts of a number of nights in succession. After several nights of observation 13 rats were caught alive. Two of these died, eleven were marked with distinctive individual patterns clipped in the fur and released. On subsequent nights the eleven individuals were frequently identified visiting the bait. Frequent consumption of wheat while the 13 rats were present and also the period of their captivity, it seemed that the total rat population was 32 to 37, a figure which was confirmed by other methods. It is a new Cholera source, interesting that the author has developed a possible method of estimating the population of wild rats.

The watch continued every night after the eleven marked rats had been baited. With one exception they were frequently seen visiting the bait. Some of the differences were observed between individuals for instance, the number of visits that a rat pays to its feeding place per hour or per night. The author is satisfied that in spite of illuminating, trapping and watching the rats, the behaviour is not prejudiced and that the behaviour of the rats was not affected.

The purpose is not to do so much for the facts as it is but because it is a method which helps to develop a usual fresh point of view.

fatality rate. The table shows the results observed in septicæmic rats; these are classified in accordance with the number of colonies grown from 0.25 ml. blood cultured by a method described in the paper.

	Group I (1-10 colonies)			Group II (11-300 colonies)			Group III (over 300 colonies)		
	Cases	Deaths	per cent.	Cases	Deaths	per cent.	Cases	Deaths	per cent.
Serum ..	29	7	(24.1)	30	17	(56.6)	12	12	(100)
Sulphathiazole	41	9	(21.9)	61	23	(37.7)	30	23	(76.6)
Sulphadiazine	4	1	(4.1)	1	4	(19.0)	16	8	(50.0)
Streptomycin	1	0	(0.0)	9	0	(0.0)	11	3	(27.2)

Sulphapyridine gave less satisfactory results than the other sulphonamide; sulphamerazine gave much the same results as sulphathiazole, but the number of cases treated was small. Sulphadiazine was regarded as the best of the sulphonamide drugs, and streptomycin is found to be the most effective drug in the treatment of bubonic plague in the light of present-day experience.

The dosage of sulphadiazine usually employed was 4.0 gm. initially followed by 2.0 gm. four hours later and then 1.0 gm. every four hours till the temperature had remained normal for two days, but the maximum duration of the course was 10-12 days. Treatment with this and the other sulphonamides was oral when possible; parenteral administration was reserved for patients unable to swallow and it was considered advisable to give an initial dose of 2.0 gm. intravenously in every severe case.

[The above dosage differs from that recommended previously by SORRY and the author viz. 2.0 gm. every four hours (this *Bulletin* 1947 v 41 415).]

Streptomycin was given intramuscularly; the initial dose was two-thirds of a gramme then one-third of a gramme every four hours till the temperature remained normal for 24 hours. In severe cases the full initial dose was given every four hours till the temperature had remained normal for two days. The total dosage varied from 4.0 gm. to 25 gm. but the latter was needed in only one exceptional case. Two patients developed a temporary psychosis, and another had a mild dermatitis, otherwise there were no toxic symptoms. [See also this *Bulletin*, 1948 v 45 597.]

LESLIE

On J. H. Alberta: the only Rat Free Province in Canada. *Canadian Public Health*, 1948, Sept., v 39 No. 9 367-74 4 figs.

This is a preliminary note dealing with a study of the remarkable circumstance that rats have not yet succeeded in establishing themselves in the Province of Alberta in Canada.

The first invasion of Western Canada by rats is said to date from about 1900, since when a progressive extension of their range has occurred from Minnesota and the Dakota territory. The invasion is found to be arrested or retarded by mountain ranges and rivers and by the intervention of uninhabited areas; it is accelerated when overcrowding among rats compels them to wander in search of food. Rat-proofing is an important factor in preventing the entry of rats into a new area, but other control measures like trapping and poisoning tend to drive them out into adjacent uncontrolled areas and so to speed up the spread of the rats.

Large-scale programmes of rat exclusion and rat control are believed to have a prospect of success in excluding rats from the Province

Rats have often been reported from different places in Alberta during the past 40 years, but on each occasion they have been detected and destroyed, thanks to the high degree of rat-consciousness existing among the inhabitants

The author recommends the setting up of a rat-exclusion campaign in the strip of land on the west bank of the South-Saskatchewan River 50 miles east of the provincial border, he points out that the discovery, in 1939, of plague infection among prairie gophers (*Citellus richardsoni* Sabine) in the province indicates that the introduction of rats would create a serious risk of the spread of infection to man

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

YIN HUAN. Problems of Amoebiasis. *J. Chin J. Med. Sci.* 1948, Oct. 2, No. 10 641-51 [23 refs.]

A general review

CARRERA G. M. & CHANGUY G. W. Demonstration of Acid Phosphatase in *Entamoeba histolytica*. *Proc. Soc. Exper. Biol. & Med.* 1948, July 1, v. 68, No. 3 610-11 1 fig.

The presence of acid phosphatase in *E. histolytica* has been demonstrated by a modification of Gomori's histochemical method.

MELLO L. da S. A amebíase e o sinal do hipogástrico esquerdo subjéctivo. [The Left Hypogastric Sign of Amoebiasis.] *Rev. Brasileira Med. Rio de Janeiro*, 1948, July 1, 5, No. 7 516-19

In patients who have suffered from amoebic dysentery pain can often be elicited by palpation over the left hypogastrium along the descending col and sigmoid. The author here however refers to subjective pain in this region complained of when the patient undertakes some spontaneous exertion exercises dancing bicycling or children running about a pain felt at the side. He avers that even though faecal examination yield no positive sign of amoebiasis such may be found later and treatment for this condition often cures completely. The transitory nature and the spontaneity of the pain would seem to be the important characteristics for there are many other possible causes of pain in this region. Cases are referred to which illustrate the author's thesis.

H. Harold Sack

CLARK, R. H. P. BEHRENDT, Z. T. & JONES R. F. Pneumo-Peritoneum in the Diagnosis of Amoebic Liver Abscess. *Amer. J. Trop. Med.* 1948, July v. 28 No. 4 545-50 4 figs.

The apparatus consists of two bottles with rubber tubing, a water manometer and an adapter for the sterile tube and needle which convey the air to the peritoneum.

The patient is prepared by a prior hypodermic injection of morphine. The site of election for introducing air into the peritoneum is about 1 inch below the umbilicus and almost the same distance to the right of the midline. A 18- or 20-gauge needle is used. It is essential that the air be flowing through the needle at the time it is introduced into the peritoneum and the pressure should be maintained at about 10 cm. of water. This will prevent contact with the bowel and consequent injury. When the peritoneum has been entered there is a sudden drop of 5 cm. in the manometric pressure. During the time the air is introduced the pressure should be adjusted to 10 cm. of water and about 400 cc. to 1000 cc. of air would be given depending on the size of the patient.

A total of 70 patients has been studied. Those cases selected include—

(a) Irregularities of the diaphragmatic shadow in which pneumoperitoneum revealed the dome of the liver to be normal in contour.

(b) Changes in the contour due to amoebic hepatitis with adhesions between the liver and diaphragm.

(c) Amoebic abscess of the liver showing the cavity with air following aspiration of pus and pneumoperitoneum revealing the relationship of the diseased liver to the diaphragm.

(d) Carcinoma of the liver for comparison.

In the third group (c) one patient, an Indian male, is included. He had an amoebic liver abscess from which 4,600 cc of pus were removed by aspiration.

In this case, 1,000 cc of air were introduced into the abscess cavity. A pneumoperitoneum with 500 cc of air was performed. In the postero-anterior view the abscess cavity only was visualized, while in the lateral view there was evidence of adhesions between the liver and diaphragm. Further evidence of adhesions was seen in the right lateral decubitus view.

It was possible to show the amount of remaining liver tissue by the combined use of pneumoperitoneum and injection of air into the abscess cavity.

The advantage of pneumoperitoneum is well demonstrated in the diagnosis of a case of carcinoma of the liver which shows the carcinomatous nodules on the dome of the liver clearly.

P Manson-Bahr

TJONG NJAN HAN. Het tropische leverabsces [Tropical Abscess of the Liver] *Med Maandblad* 1948, Aug 1, No 25, 504-8 [14 refs] English summary

Twelve tropical liver abscesses occurred in men only between the ages of 20-50 years in Soekabumi, Netherlands East Indies. As regards race, five were in Chinese, six in Sudanese and one in an Ambonese. Eight of the abscesses were situated in the right lobe, four in the left. One ruptured into the abdominal cavity, another through the abdominal wall to form a tumour-like growth in the surrounding skin. In one a subphrenic abscess developed. Three caused a distinct bulging of the abdominal wall while two gave rise to a considerable abscess. The associated temperature was not high and in some it was normal, but the relatively increased pulse rate constituted a valuable differential diagnostic sign. A high leucocytosis was recorded in three cases, but in the others the leucocytes ranged from 3,000 to 8,000 per cmm. Amoebae or cysts were found in the faeces in 33 per cent.

In nine instances active amoebae were found in the pus and in one, it is emphasized, cysts of *E. histolytica* were present in the 'prune-juice' pus, as well as in the yellow pus.

In the majority of cases the liver abscess probably develops at least 4-5 years after the amoebic dysentery.

Treatment consisted of the evacuation of the pus, drainage and sometimes irrigation with emetine followed by a combined course of emetine injections with quinoxal (Atron) and iodoquinol by the mouth.

P Manson-Bahr

LUIS CARRILLO. Amoebiasis intestinal y alergias respiratorias [Intestinal Amoebiasis and Respiratory Allergy] *Revista Med Argentina* 1948, July 30, No 31, 1477-82 [20 refs]

An interesting record. The author notes that among 120 patients who were passing *E. histolytica* or its cysts there were 12 who suffered from symptoms of respiratory allergy, 4 with spasmodic attacks of asthma and 9 with other allergic symptoms: cutaneous, digestive, nervous, etc. Six cases are described fully. These may be summed up by saying that they showed the usual signs of allergy and tests were made with a large number of substances—dusts, pollens, milk, animal hair, vegetal substances, etc.—with varying results. The usual antispasmodics were tried with perhaps temporary but no permanent benefit. Usual examination having revealed the presence of *E. histolytica* or its cysts, treatment was prescribed and followed by Atron 105. In each case a good remission was obtained and in 1 was maintained.

- BEEMER, L. M. SAMUEL, E. & SHEEDROW A. The Secondary Infection in Chronic Amoebic Colitis. A Clinico-pathological and a Radiological Study. *South African Med J* 1948, Oct. 9 v 22, No. 19 61 (17 figs. [28 refs.])

The medical histories of five cases of colitis seen in S. Africa are recounted in detail and, apart from suspicion on what appears to be flimsy evidence, the instance has it been proved, either by faeces examination, or by sigmoidoscopy that *Entamoeba histolytica* played any part in the causation of symptoms. It may be justly asked upon what was the title of this paper founded? The reader is left to infer that the radiographic appearances afforded by barium enemata were regarded as conclusive. If this is so then the whole *raison d'être* of the ground and the critic is left wondering what could have prompted the sweeping assertion that 'It is probable that although *Entamoeba histolytica* causes the original pathological lesion secondary infection alone is responsible for clinical symptoms. The criticisms which are directed to the radiographs which illustrate this paper are these—Small filling defects are produced in most forms of colitis but usually in Europeans the amoebic ulcerations are superficial and the actual lesions so small that no distortion of the mucosal outline is produced. This statement also applies to the irregular outline of the cone-shaped appearance of the caecal caecum on which stress is laid. This is seen in other forms of chronic intestinal disturbance, whilst the ragged outline of the transverse colon in fig. 4, and the saw tooth edge of the descending colon in fig. 7 are clearly those of diverticulitis. The hard fact emerges that except in the most advanced stages with extensive and deep ulceration and where anatomical alterations have been produced, no radiological picture typical of intestinal amoebiasis can be said to exist. This is a detailed study of ten years' work in the Belgian Congo on the control of leprosy which brings out the following points from the experience

vessels and in the production of fibrous tissue. There is a condition caused by the authors pan-vascularitis with perivascular accumulation of lymphocytes and histiocytes crammed with lepra bacilli. There is a chronic interstitial neuritis. Large foamy cells are seen and many with still larger vacuoles. "Gravure cheese appearance" and giant cells and, terminally fibrosis and hyalinization.

Seeing that this condition of the nervous tissue is so marked in the lepromatous form, the authors are of opinion that the neural type as a term for a separate clinical variety should be dropped. *H Harold S-C*

In the test for leprosy by injection of histamine the weal produced is accompanied in the healthy skin by itching but not in the non-characteristic or tubercloid form of the disease. The author has observed that in negroes and those with a dark skin where colour changes on histamine injection are not distinct 5 per cent. formic acid gives a similar and even more marked effect. If one deposits a drop of the acid on normal skin and then pricks the skin with a needle through the drop a slight burning is felt then an erythema appears followed after a varying interval by an itching papule and very marked redness. In leprosy patients such a procedure results in the weal formation but no itching. Intracutaneous injection (0.01-0.02 cc. of the formic acid solution into healthy skin causes a marked sensation of burning lasting several minutes and due to the caustic action of the acid. This is absent in the anaesthetic skin of a leprosy patient. The author believes this to be a valuable test in those suspected of leprosy the colour of whose skin makes it difficult, perhaps impossible to determine the histamine reaction.

LU Shang Ho. On the Value of Superficial Nerve Hypertrophy in the Diagnosis of Leprosy. *Chinese Jour. Trop. Med.* 1943 Jan. v 1 No. 1 29-42 3 figs.

This paper deals with extensive examinations for thickening of superficial nerves in Chinese subjects for the diagnosis of leprosy. Those searched for include the supra- and infra-orbitals, great auricular, ulnar, median and radial, peroneal and the tibial. In 3,077 healthy children of 8 to 15 years of age the nerves of the arm and leg and the great auricular were more frequently felt and the infra-orbital least so. Among 8,990 healthy adults the results were much the same except that the supra-orbital nerve was more rarely affected. Thus it was found that such nerves can be felt in a great number of healthy persons and the numbers are larger in men than in women and children. Those on both sides are perceptible more frequently than on one side in both sexes.

goes on an antimonial is administered Adult worms, living and dead, and large quantities of ova pass out by the drain, which is left for 20 days, the tube is then removed and in a few days the opening closes The patient attends as an outpatient for gentian violet treatment as above and after 4 weeks the Fouadin injections are repeated

The author states that in the past three years he has treated in this way 12 patients with complete success and no relapses *H Harold Scott*

AUDOYE & DESSAUSSE Sur un nouveau cas d'infestation par la grande douve du foie "*fasciola hepatica*" [A Case of *Fasciola hepatica* Infestation.] *Bull et Mém Soc Méd Hôpit de Paris* 1948, Nos 26/27, 920-23

A "classical" case, followed up in Cherbourg for 4 years

CASTRO JENKINS, A Fascioliasis hepatica humana en Costa Rica (Presentación de un caso) [Human Fascioliasis] *Rev Kuba Med Trop y Parasit*, 1948, Aug, v 4, No 8, 160-61, 1 fig

This is said to be the first autochthonous case in Costa Rica

GALLIARD, H La distomatose intestinale humaine à *Fasciolopsis buski* au Tonkin [Human Infection by *Fasciolopsis buski* in Tonking] *Bull Soc Path Exot* 1948, v 41, Nos 3/4, 214-17

Infection of man by *Fasciolopsis buski* is relatively common in parts of China, Formosa, Siam, Borneo and Sumatra, Assam and Bengal, on the other hand, it is generally recognized as being very rare in Tonking

The author, with DANG-VAN-NGU [this *Bulletin*, 1942, v 39, 13] has reported 5 cases originating in Tonking In three cases the infection was discovered during post-mortem examinations, in one during a gastro-enterostomy, and in one by finding eggs in the stools and subsequently the adults after treatment with oil of chenopodium He now reports two other cases In one patient who suffered from alternate diarrhoea and constipation, eggs were found in the mucus that surrounded a constipated stool He was not successful in eliminating the adults, but the eggs diminished after treatment It was not possible to follow this case for long

The second patient was in hospital with jaundice and hepatitis he vomited a worm, numerous eggs were found in the stools, and at autopsy 3 worms were recovered from the duodenum and 3 from the jejunum

The author discusses the anomaly that in the routine examination of tens of thousands of stools these very characteristic ova have not been found and yet the infection, though rare, does exist Further, there is a great disparity between the infection in man and the pig In the latter it is relatively common in Tonking the author found 12 per cent and 47 per cent in March and December in Hanoi, and 11 per cent to 35 per cent in North Annam It is possible that the parasite is ill-adapted to man, but all the specimens he has examined show full development It is possible that there are two species, a common one found in the pig and a rare one found in man, but again the only difference he has found is in size, the specimens in man being larger This is however a common experience in parasitology and in a single pig there is a great variation in the size of the worms recovered

The most simple explanation for the rarity of this infection in Tonking is that the aquatic plants, on which the cercariae encyst, are eaten cooked and the envelope of these plants is not opened by the teeth as in other endemic areas, but opened with a knife

he must be supported by the administration. The most important method of education is by personal discussion with small groups of people or even individuals and the most powerful weapon in overcoming apathy (which, more than hostility is the main enemy) is persistent badgering.

PESIGAN T. P. Schistosomiasis Reconnaissance in Northwestern Mindanao. *J. Philippine Med. Ass.* 1948 Sept. v 4 No 9 493-503 map (10)

The author who recently confirmed the existence of a focus of *S. japonicum* infection in South-eastern Luzon, Philippine Islands [this *Bulletin* 1948 p 622] was told by a physician that there were suspected cases in North-western Mindanao. He therefore made a tour of the area around Pangasinan Bay staying there for about 2 weeks and examining the faeces of 304 persons in the villages visited. The examinations consisted of 4 direct cover-slip preparations and in this way positive results were found in 111 of the persons examined. This figure should not be regarded as an indication of the incidence in the population as a whole since the persons examined had symptoms suggesting the infection but the rate is high in view of the fact that there had not been any previous confirmation of cases from the area.

Oncomelania quadrass were found in several places some of them in association with fork-tailed cercariae.

Endemic foci are most likely to be found in low level, wet plains, without dry season suitable to the cultivation of lowland rice. A map showing 4 types of climate and the known foci is given for the Philippine Islands as a whole.

Intestinal infection was found in 70 per cent, hookworm in 63 and Trichinella in 34 per cent. of the people examined. 7 patients had *Entamoeba histolytica*, 2 *Balanitidum coli* and 1 *Paragonimus*; a few other infections were also diagnosed.

NARDONE P. M. La distomiasi sinense. Contributo allo studio delle distomiasi. *Clonorchis sinensis* nell'estuario dello Yangtze-kiang e nella città di Shanghai. (Cura chirurgica con fistola biliare terapeutica). [*Clonorchis sinensis* in the Yangtze-kiang Estuary and in the Shanghai District.] *Ann. d. Ist. Var. e Colon.* 1948, Jan-Apr v 53 No. 1 69-78. [17 refs.]

The only part of this article on infestation by *Clonorchis sinensis* which was new to readers of the *Bulletin* is that dealing with treatment. Hater-gentian violet has been recorded as beneficial in some cases but most workers have agreed that no satisfactory treatment is known. The author finds drug treatment unsatisfactory though antimonials such as Fovadin may help. The only treatment which he found really a failing was surgical. In early cases and with mild infestations he has obtained cure without relapse in 8 patients by the following method. Preliminary injection of Fovadin to test susceptibility and if there is no reaction 5 cc. are injected on alternate days to the tenth day or dose but probably the latter from what follows. Then gentian violet is given in capsules by the mouth at a total 13 gm. 40 mgm in 20 days and, after 10 days interval, another 10 phials of Fovadin followed, a further 10 by the gentian violet. All through, 6 tablets of Normo-heparin are given daily as a cholagogue.

In more advanced cases such treatment is insufficient and in view of the infestation ending fatally or of it producing cirrhosis or carcinoma, surgical intervention is called for. Drainage by duodenal sound is impracticable because this cannot be continued for an indefinite period. The author's procedure is as follows. With local anaesthesia he seals off and then opens the gall bladder and drains it externally by Pezzer tube. At the same time as the drainage

goes on an antimonial is administered. Adult worms, living and dead, and large quantities of ova pass out by the drain, which is left for 20 days, the tube is then removed and in a few days the opening closes. The patient attends as an outpatient for gentian violet treatment as above and after 4 weeks the Fouadin injections are repeated.

The author states that in the past three years he has treated in this way 12 patients with complete success and no relapses. *H Harold Scott*

VON BOXSCHKE B. Folic Acid in the Treatment of Pernicious Tapeworm Anaemia. *Diphyllobothrium latum* and Pernicious Anaemia. XI. *Acta Med. Scand. supplica* 1948, v 131 Suppl. 213 82-90 4 figs.

The author states that there is no report in the literature on the effect of folic acid (pteroylglutamic acid) in the pernicious anaemia due to *Diphyllobothrium latum* infection. He reports on 4 such cases treated with this substance. In three the diagnosis was certain as the subjects were young and all had free hydrochloric acid in the gastric juice at some time. The fourth patient (aged 57) had no free acid and may have been a case of "cryptogenetic" pernicious anaemia associated with the worm infection.

In all four there was a dramatic response to folic acid 1, 20 to 30 mgm per day for 7 to 10 days. There was a sharp reticulocyte response in 3 cases the highest being 31.1 per cent. on the 7th day and in all three there was a rapid rise in erythrocytes and haemoglobin. The worm cure was affected with Fibra 3.5 to 4.0 gm. at a later date. The removal of the worms had no effect on the rate of rise of the erythrocyte curves.

The author points out that it has previously been shown that the response of tapeworm pernicious anaemia is as good as that of cryptogenetic pernicious anaemia to liver extracts and stomach extracts by mouth but not to gastric juice and meat. He has shown that the patient with tapeworm anaemia secretes intrinsic factor but that the tapeworm checks the reaction between the intrinsic and extrinsic factors. It has however no effect on the combined anti-anaemic factor. He considers that it is probable that the tapeworm affects the conjugase which in normal person converts pteroylglutamic acid (vitamin B₁₂ conjugate) into pteroylglutamic acid (folic acid). L. E. N. FINA H. A Helminth Survey from an Autopsy Series on Natives of Okinawa, with Comments on Complications of Ascaridiasis. *Amer. J. Trop. Med.* 1948, July v 21 No 4 383-8. 10 refs.]

In the course of 120 autopsies on natives of Okinawa, after H. invasion the incidence of helminth infections was studied by the author. He compares his results with the findings in the same or neighbouring areas (at autopsy of

y egg counts in the living) of BENJAMIN (U S Nav Med Bull, 1946, v 46, 95), STEINER (Arch Pathology, 1946, v 42, 359) and FRANKS *et al* [this Bulletin, 1948, v 45, 453]

In the present series, the author found 98 helminthic infections in 68 persons. The nature of these is shown in a table which also gives the figures reported by the authors quoted above. It is noted that hookworms were found in 15.8 per cent of the present author's cases, *Ascaris* in 25.8 per cent and *Trichuris* in 8 per cent. The average percentage finding of *Ascaris* by the previous three workers was about 44.

The author gives particular notice to findings relating to *Ascaris* and of the parts of the body in which they were found. *Ascaris* was directly responsible for 3 deaths, two from intestinal obstruction (each focus of the distended bowel showing a score or so of worms) and one from hepatic infarction, which it is claimed, is a newly described complication. In this case, an *Ascaris* was found triply folded in the left hepatic duct, which it had dilated. The surface of the left lobe of the liver beneath showed two dentate-shaped haemorrhagic areas, and the cut surface showed a friable haemorrhagic area extending to the inferior surface at the hilum. A small friable thrombus was present in the left branch of the hepatic artery near the dilated duct.

The author notes, and quotes the evidence of other workers to confirm his observation, that the biliary tract of the Okinawan could be dissected with comparative ease, and that the duct system is relatively dilated. He suggests that migration of *Ascaris* is facilitated by this relative dilatation of the duct system. Neither flukes nor calculi were found in any of the 120 cases.

Migration into the biliary tract was also observed in a second case, but without gross changes.

In the 31 cases of ascariasis, *Ascaris* was found at all levels of the gastrointestinal tract from the mouth to the anus. The worm burden varied from 1 to 50. Occasionally a worm was found in the larynx.

The presence of biliary tract invasion by *Ascaris* is discussed and references to it in the literature are given. Among the observers quoted is GIRGES [this Bulletin, 1935, v 32, 257] who, in addition, has listed 21 complications due to this nematode.

The author concludes that helminth infection is present in about 80 per cent of the living population of Okinawa, and that the incidence found at autopsy is about 60 per cent. About half of the population showed multiple infections.

H J O'D Burke-Gaffney

BEACH, E W. Genital Manifestations in Early Filariasis. *J Urology* 1948, Mar, v 59, No 3, 371-5

In Noumea, New Caledonia, a Marine battalion of the U S forces which had come from the Russell Island campaign and had previously been trained in Samoa was surveyed in connexion with a symptom complex from which 160 of 385 men were suffering. This was eventually shown to be due to filariasis.

The condition was characterized by recurrent attacks of lymphangitis and lymphadenitis. The former was often descending or centrifugal in type. Recurrent attacks caused thickening and nodosity of the lymph vessels and enlargement and tenderness of the glands. There was no great prostration and no pyrexia. The glands commonly involved were inguinal (in 147 cases), femoral (108), epitrochlear (56), and axillary (132). The brachial lymph vessels were involved in 78 cases.

Thirty-seven men showed genital involvement. Acute vasitis or funiculitis was most common and occurred in 19 cases, in 3 of which it was bilateral. It began suddenly with pain and tenderness in the structures near the internal

ring and in a matter of hours had rapidly descended through the urethral canal and into the scrotum." There was apparently considerable thickening of the vas. In the recurrent cases the thickening was noted irregularly along the course of the vas. Biopsy showed that the vas itself was not actually thickened but that there was involvement of the surrounding tissues. Epididymis was usually not involved, but a characteristic finding was a "rolled up dough-like mass of tunica vaginalis" just beneath the globe testis which persisted after the attack subsided. The testis on the affected side was tense, swollen and very sensitive. There was an increase of hydrocoel fluid on aspiration the fluid was clear and did not contain microfilariae. The attack of funiculitis usually lasted 3 to 4 days. Microfilariae were found in the testis around the vas in 3 out of 5 biopsies.

[The parasitological aspects of this paper should be accepted with caution since it includes the two following statements: "It is remarkable to examine a blood smear from a native to find the field literally alive with squaring adult forms" and "Neither the presence of the adult worm nor the microfilaria had ever been demonstrated in the tissues of a white man." From the context however this last statement might be taken to refer only to the series under review.]

L. E. Nisbet

HAWKING F., SEWELL, P. & THURSTON, June P. Mode of Action of Hetrazan in Filariasis. *Lancet* 1948, Nov 6 730-31

In cotton rats infected with *Litomosoides carinii* the adult worms reside in the pleural cavities while the non-periodic microfilariae float in the peripheral blood. When these rats are treated with Hetrazan in doses of 25 mgm. per 100 gm. intraperitoneally the numbers of these embryos in the peripheral blood diminish. When, however 8 mgm. per 100 gm. are injected intravenously this diminution is extremely rapid—80 per cent. disappear in one minute and over 90 per cent. in two but even after the most intensive treatment a few microfilariae persist. Similarly the pleural cavities still contain many dead and apparently healthy microfilariae in the vicinity of the adult worms. It appears that these form a reservoir from which the supply in the blood is being constantly replenished. Hetrazan exerts only a moderate effect on the adult worms so that prolonged intensive treatment is necessary and even then many of the worms escape.

Microfilariae can be maintained alive for several days at 37°C. in serum plus Ringer's solution and glucose but when Hetrazan is added it has no apparent direct effect upon them—neither has serum from Hetrazan-treated rats any effect. Further studies made from the examination of the distribution of microfilariae in different organs revealed that in Hetrazan-treated rats the microfilariae congregated in the liver probably in the sinusoids. When the rat were killed six hours after treatment, many microfilariae were surrounded by phagocytes which were attacking them. The lungs form a special case in cotton-rat filariasis as they constitute the chief port of entry for the microfilaria from the extravascular spaces (pleural cavities) into the circulation and their microfilarial content is correspondingly high.

It is concluded that Hetrazan acts by modifying the microfilariae in some way so that they are seized by the phagocytes of the reticulo-endothelium and presumably destroyed. In this respect its action would resemble that of opsonins. Microfilariae which are removed from contact with phagocytes are not speedily affected by hetrazan.

The chemical or physical reactions underlying this "opsonizing" effect of hetrazan are unknown, but they must be rapid in their action.

P. Manson-Ball

NDBERG, K. Seconde enquête épidémiologique sur la draconculose dans l'Inde [Second Epidemiological Investigation of Dracontiasis in India] *Bull Soc Path Exot* 1948, v 41, Nos 3/4, 282-93

A study of dracontiasis was undertaken in Vangarvadi, a village in the State of Hyderabad. It is situated on the banks of a river which is dry for most of the year. The rains, which are not abundant, form ponds which dry rapidly. As a general rule, water is found near the village only from June to September—August to October. Most of the inhabitants obtain their water from a single well in the bed of this river. The villagers descend steps to reach the water in this well.

The Hindu inhabitants, Mahratta cultivators, almost all belong to one caste. There are certain Mussulman families. There are also untouchables (Mangs) who are forbidden to use the well and obtain their water from ponds while it is available, but during the driest seasons they have to use water from the well, and the Mahrattas pour into their storage tanks without touching them. Thus, the whole village drinks water from this well at some time during the year. Boiling of water is almost unknown and the inhabitants seldom filter the water effectively, so that they are all subject to infection from this well.

The total population of the village was 700 to 800, but without official support the author was only able to study 310 persons. Of these 82, or 26.4 per cent, had been affected with dracontiasis.

The data are given in tabular form, some points from the digestion of these tables are given below—

Below the age of 5 years, one child was affected. Nine persons had their first attack at the age of 5, and 7 at the age of 6 years. At the succeeding ages 7 to 20, the following were the incidences of first attacks—1, 1, 4, 3, 0, 2, 0, 3, 5, 0, 1, 2, 3 and 7. At ages from 21 to 36, there were 18 first attacks and one at each of the ages, 49, 63 and 68. Four persons had their first attack "during infancy" and 7 could not state the age of their first attack.

The number of worms from which each individual suffered were as follows—one worm—19 persons, two—18, three—6, four—5, five—2, six, seven and eight—1 each, ten—2, twelve, thirteen, sixteen, eighteen, twenty-five and thirty—1 each, thirty-five—3, forty and sixty—2 each, sixty-five, eighty, one hundred, one hundred and sixty and two hundred—1 each. In 9 cases there were "many worms" but the number was not known.

Thirty-two persons had suffered from dracontiasis for one year, thirteen for two years, four, four and five for 3, 4 and 5 years, respectively, and eighteen for more than 5 years, the longest period being 50 years.

The maximum number of worms in one year were one in 32 cases, two in 19 cases, three in 10 cases, four in 4 cases, five in 4 cases, and seven or more with a maximum of 50 in the remaining 6 cases, in seven this number was not determined. The localization of the worms was as follows—Feet—23, ankles—71, legs—81, knees—43, thigh—24, buttock—4, upper limb—26, of which 18 were on the left side, trunk—15, genitalia—10, and head and neck—4.

The author asks why it is that when all were subjected to infection from this well more or less continuously, only a proportion showed infection at any time of their lives, why some have heavy infections and some light, and finally why some are infected early in life others late? Unfortunately, those who had escaped entirely would not allow any examination. [The author gives no indication of the caste distribution of the patients.]

DEFICIENCY DISEASES

TROWELL, H. C. Medical Examination of 500 African Railway Workers.
East Afric n Med J 1948 June & Aug v 25 Nos. 6 & 8 762-764
 711-21

1. This paper presents in terms intelligible to the layman the background and general conclusion of the medical survey. Climate, conditions of work, housing, psychological stresses and prevailing diseases are briefly described. Details of the diet are to be reported separately. Briefly, the rations issued consisted only of maize-meal and meat and supplements which workers had to be bought out of wages. Trowell criticizes this system, since abundant and says—"everything suggests that Africans can arrange their own diet much better than has been arranged for them by Europeans in basing it on any system of rations."

By supplementing the ration the workers were achieving an adequate and nearly adequate diet. This however is not the whole story. Clinical and pathological studies have shown that the syndrome called by Trowell "malignant malnutrition" is very common in East Africa. It is characteristic of this disease that its effects are widespread throughout the body and they are permanent. Thus, in considering the causes of inefficiency and ill-health in Africans it is necessary to take account of the past as well as the present of the previous dietary background and of old injuries resulting therefrom. "Almost the whole of the medical report must therefore turn on the evidence of malignant malnutrition."

The African child is handicapped in his development before and after birth. It is only during 6 months of breast feeding that for one long period in his life he achieves parity. Thereafter he passes through a period of malnutrition which damages many internal organs to an extent he cannot assess by present techniques. Not only the body but the development of mind as well may be injured. The whole weight of the clinical and pathological evidence supports the contention that many if not the majority of Africans have suffered and may still suffer from a disease which has left not only scarred and crippled internal organs but scarred and crippled mental attitudes and reactions. Hence the apathy and lack of initiative so often noted in African adults. The vicious circle is established of low work, low wages, malnutrition, poor living conditions.

II. In the second paper are given the results of the clinical examination for signs of malnutrition. For the general reader the interest will probably be not so much in the findings themselves as in the discussion of diagnostic criteria, and of the difficulties encountered in nutritional surveys. In particular there is a detailed description of cracked skin or mosaic skin and of the points which differentiate it from crazy-pavement dermatosis.

The results are classified under two headings—recognized and doubtful signs of malnutrition. There was no clear-cut evidence of calorie or protein deficiency. More than a third of the subjects showed alteration in the conjunctiva—thickening, pigmentation, vascularization and dryness. In three per cent., foam-like plaques were present as well—these cases were classified as xerophthalmia. 33 per cent. of the employees had follicular keratosis of varying degree and in 24 per cent. there was xerosis of the skin. These skin and conjunctival changes are listed under the heading of vitamin deficiencies. There was no evidence of vitamin B deficiency. Signs of avitaminosis were uncommon, cheilosis being present in two per cent. and corneal vascularization in three per cent. In a few subjects there were mild changes in the tongue attributed to nicotinic acid deficiency, such as swelling, localized bare areas, redness and hypertrophy of papillae. Classical pellagra was not

seen, and there were no cases of scurvy. Parodontal disease and non-scorbutic gingivitis were, however, common. There was no evidence of rickets, no proven case of rickets has in fact ever been found in an African in East Africa. The iron intake was adequate, since the diet consisted largely of maize, and there was no clinical evidence of anaemia. Although the calcium content of the ration was low, there were no clinically apparent effects of calcium deficiency. Active dental caries was present in only six per cent.

The remaining sections are devoted to signs of uncertain origin, which were found as follows —

Hair—loss of texture	12 per cent
Hair—loss of texture and some loss of colour	4 "
Crackled skin (all grades)	42 "
Enlargement of the liver	2 "
Gynaecomastia	5 "
Parotid enlargement, moderate or marked	18 "

A technique is described for detecting and estimating the degree of parotid swelling.

[It is to be hoped that the introductory paper will in fact be read outside purely medical circles for the problems discussed in it with clarity and force are important not only to doctors. The emphasis on the psychological results of malnutrition is welcome. We are no longer concerned only with frank deficiency disease, but more and more with suboptimal health, in which the physical signs may in themselves be insignificant. They serve, however, as clues, pointing to disabilities that we cannot yet assess. During the war some work was done on the relation of nutrition to performance and behaviour (FRANKLIN, SCHIELE, BROZEK, & KEYS, (1948) *J Clin Psychol* v 4, 28) but only the surface of the field has been scratched.

Trowell implies that malnutrition is the point at which to attack the vicious circle of low work, low wages, low food. The challenge is not lightly made, for he goes on to say of malignant malnutrition that the cause is unknown, the prevention uncertain, the cure often impossible. The disease is not to be explained by current nutritional concepts, with many of which it is in sharp conflict.

The second paper illustrates the incompleteness of our knowledge in a different way. A severe critic might argue that almost every one of the positive findings recorded in the survey should be listed under the heading "of uncertain origin". For instance, not all workers would agree that the conjunctival changes described are caused by vitamin A deficiency. KRUSE [see *Bulletin of Hygiene*, 1942, v 17, 115] believes that they are, but PLATT prefers to use the non-committal term "excess tissue" [*ibid*, 1945, v 20, 412]. The literature suggests that the clinical appearance is not identical with xerophthalmia in the Far East, and there are differences in natural history. "Excess tissue" never goes on to keratomalacia, it is less common in the young, and more common with pterygium, which in Europe is regarded as a senile change. Whatever the origin of "excess tissue", it seems to be an example of the generalization, that the effects of malnutrition mimic those of senility. The question now arises, is this true also in the psychological sphere?]

J C Waterlow

ALTMANN, A & MURRAY, J F. The Anaemia of Malignant Malnutrition (Infantile Pellagra, Kwashiorkor). Protein Deficiency as a possible Aetiological Factor. *South African J Med Sci* 1948, June, v 13, No 3, 91-113, 8 figs (4 on 1 pl) [80 refs]

Haematological investigations were carried out between October 1946 and January 1948, in the Johannesburg non-European Hospital, upon 34 children

suffering from gross nutritional disorders. Thirty-one of the cases were typical of the "malignant malnutrition" syndrome with oedema, rash, mucous membrane and hair changes; the remainder were cases of uncomplicated nutritional oedema.

Anaemia was found in all, but was of only moderate degree even in those who were very severely ill. It was mostly normocytic in type (23 out of 34 cases); 4 of the children had a microcytic blood picture while 7 were macrocytic; a fourth became macrocytic while under observation.

Only 8 of the 17 bone marrow specimens examined showed abnormal cells suggestive of the megaloblastic anaemia associated with lack of liver principle or folic acid, and of these only 2 occurred in cases with macrocytic anaemia. The abnormal marrow cell were of intermediate type rather than typical megaloblasts and even when present they were never predominant.

Treatment consisted almost entirely of dietary improvement. Skim lactic acid milk was used. This induced a reticulocyte response in 9 cases; clinical response was rapid and satisfactory.

During the early part of the recovery phase there was frequently a drop in haemoglobin level and in red cell count, which is interpreted as being due to an early rise in plasma volume outstripping the rate of regeneration of red cells and haemoglobin.

On the basis of their findings the authors conclude that the normocytic anaemia in these cases is due to deficiency either of total protein or of some specific amino-acid, possibly tryptophane; and that the anaemia, together with lowered plasma volume represents a disturbance of blood regeneration due to lack of essential blood-forming materials. The occurrence of hypochromic or megaloblastic anaemias, indicative of deficiency of iron and liver principle respectively is due to the presence of complicating factors or associated deficiencies in much the same way as skin lesions and lesions of mucocutaneous functions can be regarded as being due to associated vitamin deficiencies and not as a fundamental part of the protein imbalance picture. [See WATERLOO, this Bulletin 1945 v. 45 774. Dea, J. Smith.]

KAUFMANN, C. F. & PUGLIESE, J. M. Estudios acerca de la distrofia en los niños de Lima (Peru) [Studies on Infantile Malnutrition in Lima, Peru.] *Rev. Hospital del Niño* Lima, 1947 Sept. Dec. v. 9 Nos. 52-53 17-33 11 figs. on 6 pls.

Ninety per cent. of the infants and children less than five years old, admitted for various causes to the children's hospital in Lima, were below normal weight. The weight-deficit became more frequent and more severe with increasing age. A quarter of the babies were 40 per cent. or more below weight, and a quarter of the children between two and five showed signs of multiple vitamin deficiency. This high incidence of malnutrition results from social factors, poverty, illiteracy, overcrowding, or deprivation by one or other parent.

In 10 malnourished babies a special investigation was made of the pathological physiology of the liver. Unfortunately no clinical data are given in this paper. There was a normocytic anaemia of moderate severity with little or no leucocytosis. The serum protein concentration ranged from 5.1 to 6.6 gm. per cent. with an albumin globulin ratio of 1:1.1-1.9. There was a slight increase in serum bilirubin and a reduction in serum cholesterol. Three liver function tests were made; the Manger cephalin-cholesterol test was positive in all ten cases, bromsulphthalein retention was found in one case only. In most of the babies there was impairment of glucose tolerance with raised blood-sugar levels persisting after two hours [see HODGINS & THOMAS, this Bulletin 1945 v. 45 728].

Biopsies of the liver were made in four cases. In all there was cellular infiltration of the portal spaces, with varying degrees of fatty change and vacuolation of the liver cells. There was some thickening of the walls of the portal vessels. The bile-ducts were normal. In one case, connective tissue fibres from the portal tracts were infiltrating the parenchyma, cutting up the lobules.

J C Waterloo

FERNANDO, P. B., MEDONZA, O. R. & RAJASURIYA, P. K. Cirrhosis of the Liver in Ceylon and its relation to Diet. A Review of 102 Cases. *Lancet* 1948, Aug 7, 205-11, 9 figs [17 refs]

The cases described are divided into two groups on the basis of clinical history and the appearance of the liver at necropsy or biopsy. Fifteen cases were classified as toxic cirrhosis. In 12 of these there was a history of an illness, characterized by jaundice and biliruria, preceding the onset of cirrhosis. On admission to hospital, ascites was present in all 15, oedema in 12, and splenomegaly in 3. van den Bergh and Takata-Ara tests were positive, hippuric acid excretion was reduced, in several cases to less than 25 per cent of normal. The plasma albumin concentration was low, and the albumin globulin ratio was reversed. Four patients were discharged apparently cured. In six others the diagnosis of toxic cirrhosis was confirmed by biopsy or post-mortem examination. The liver was coarsely nodular, microscopically there were collections of hyperplastic liver cells, without normal lobular structure, and separated by areas of scar tissue containing numerous bile-ducts.

The remaining 87 cases were classified as Laennec's cirrhosis and further divided into 3 sub groups, according to the stage of development of the disease. In the earliest stage, the only constant clinical finding was great enlargement of the liver, the edge being 3 finger-breadths or more below the costal margin. In most cases of this sub-group the diagnosis was confirmed by biopsy. As the disease developed, ascites became more common and oedema, splenomegaly, and haematemesis were also found. In the final stage the liver was contracted and no longer palpable. There was no clinical jaundice in this group, and bile-pigment was only occasionally found in the urine. In half the cases, however, there was a positive van den Bergh reaction, and in nearly half an increased urobilinuria. Even in the early stages the Takata-Ara test was positive, and hippuric acid excretion reduced. The plasma proteins showed the changes characteristic of liver dysfunction—a reduction in albumin and an increase in globulin. Anaemia was present sometimes macrocytic and spherocytosis was also found in a few cases. At autopsy in patients of this group the liver was finely nodular. Microscopically there was a fine fibrosis affecting particularly the portal regions and breaking the lobules up into small groups of cells. In the early stages the fibrosis was accompanied by extensive fatty infiltration.

Much attention has been devoted in recent years to malnutrition as a possible cause of cirrhosis of the liver in the tropics. For this reason the dietary history was investigated in as many cases as possible. In the first main group the diet was considered to be adequate in 8 cases, and in these the cirrhosis was regarded as a sequel to infective hepatitis. In 6 others the diet was deficient, particularly in protein and the authors comment that "it looked as if the experiments of HEMS WORTH and GLASS [see *Bulletin of Hygiene* 1944 v. 19, 584, had been reproduced unwittingly".

In the group of Laennec's cirrhosis a detailed dietary history was available in 43 cases. The diets were classified, from good to bad, as A, B, C, D. The distribution of the diets among the patients, and in 400 non-cirrhotic controls, is shown in the accompanying table.

Diet	In patients with Cirrhosis per cent	In controls, per cent
A	37	61.4
B	0	22
C	23	9.25
D	30	8.25
No. cases	43	401

About four times as many cirrhotics as control fall into group C and D. It is noteworthy also that all the cases of early cirrhosis with fatty infiltration of the liver from whom a history was available fell into category D.

These results are discussed in the light of recent experimental work on dietary liver damage and it is concluded that in these cases cirrhosis of the Laennec type was preceded by fatty infiltration caused by a diet deficient in animal protein and lipotropic factors. In some cases alcoholism may also play a part since it was commoner among the cirrhotics than in the control series.

It is impossible in an abstract to do justice to this valuable paper which contains many details that have not been mentioned here and is illustrated by excellent photomicrographs. There is a close parallelism between these clinical findings and the two types of dietary liver injury produced experimentally by HUSWORTH and GLYNN [loc. cit.]. On closer examination however the rôle of malnutrition as a cause of toxic cirrhosis in the cases described above appears open to question. For if out of the 15 patients there were 8 who were well-nourished, and were diagnosed as having infective hepatitis, why should not the 8 ill-nourished also have had infective hepatitis? The evidence, in fact, rests on two points. 8 cases out of 15 with a history of bad diet is a higher proportion than in the control series. Secondly in several of the cases the diet had been rather severely restricted for a relatively short period before the onset of jaundice. Neither of these points is conclusive in such a short series.

The evidence on the other hand, for a relation between malnutrition and diffuse fibrosis is impressive, and is the first of its kind. Hitherto nothing more positive has been established than a general correlation between the incidence of cirrhosis and of malnutrition.

J. C. B. Acland

1. NITULESCU, J. *Etat actuel des recherches sur la pellagre en Roumanie* [Present Position of Pellagra Studies in Rumania.] *Bull Acad Med Roumanie* 1947 v. 20 No. 12, 25-30. 19 ref. 1

2. — *Esquisse d'un programme d'étude et de lutte contre la pellagre en Roumanie*. [Outline of a Campaign against Pellagra in Rumania.] *Id.* 1947, 372-9

1. Pellagra is still one of the most serious endemic diseases in Rumania. In 1943 for instance 10,307 cases were recorded as attending hospital and clinics and it is thought that in 1938 the actual incidence was probably in the region of 110,000 cases. There were in that year over 3,000 deaths.

In this paper pellagra is taken to mean multiple deficiency in which symmetrical photosensitive dermatitis predominated. The symptomatology followed mainly the classical triad, but showed great variability in severity of

different symptom groups. No pathognomonic biochemical changes were discovered, nicotinic acid excretion was diminished in some cases, but this was inconstant.

The highest incidence of the disease occurs in Moldavia where the diet of country folk contains an excessive proportion of maize and is deficient in protein [see BORROW *et al* this *Bulletin*, 1948, v 45, 729].

Nicotinic acid has been found of the greatest use in treating the classically pellagrous part of the syndrome, but has to be accompanied by an all-round improvement of diet to clear up the whole deficiency state.

11 In his second paper, the author appeals for a concerted attack on the pellagra problem in Rumania. He emphasizes the necessity for field investigations to determine the full dietary pattern of the inhabitants of the areas where pellagra is endemic and the natural history of the disease.

While clinical and laboratory studies are of the greatest importance, this social scourge can ultimately be eliminated only by reforming the whole pattern of rural economy and diet. Among the measures proposed for this purpose are demonstration farms, co-operatives, domestic science schools, canteens and model bakeries.

Dean A Smith

RAMALINGASWAMI, V, MENON, P S & VENKATACHALAM, P S. Infantile Pellagra. Report on Five Cases. *Indian Physician* 1948, Sept, v 7, No 9, 229-37, 7 figs on 2 pls [27 refs]

These five babies presented all the typical features of infantile pellagra or kwashiorkor. They came from families of the labouring class, whose diet is known to be deficient, and among whom malnutrition is prevalent. The age at admission ranged from 6 months to 3 years. The main clinical features were dryness of the hair, angular stomatitis and blepharospasm, oedema, enlargement of the liver, and lesions of the skin. These are illustrated in several photographs, and appear to fulfil the criteria laid down by TROWELL [this *Bulletin* 1941, v 38, 722] for "crazy-pavement" dermatosis in Africa. The lesions consisted of pale desquamated areas surrounded by a zone of hyperpigmentation, and were found in the popliteal and antecubital fossae, in the groins, on the vulva, and on the buttocks. There was a history of diarrhoea in all the cases, examination of the stools showed nothing abnormal except for fat globules, and in one case blood and mucus.

Treatment was unsuccessful, in spite of a high protein diet, supplemented with riboflavin, thiamin, and nicotinamide by injection, all the babies died. Permission was not given for post-mortem examination.

[Three points are of interest in this paper. In the first place the report of HARE (*ibid*, 1947 v 44, 738), is confirmed, that kwashiorkor does in fact occur in India. The question, however, still remains, whether it is as common as in Africa, and if not, why not? Secondly, although it is difficult to judge from so small a series, the exceptionally high mortality supports the belief of GILLMAN and GILLMAN (*ibid*, 118) and of MAGALHÃES CARVALHO (*ibid*, 1948, v 45, 635) that pure vitamins do no good, and may in fact do harm. Thirdly, an unusual feature is that most of the babies were still on the breast at the time when symptoms first appeared—more commonly the disease does not begin until after weaning.]

VIRIRA, J R. Comentário sobre o estudo da pelagra [Comment on the Study of Pellagra]. *Anais Paulist de Med e Cirurg* 1946, June, v 51, No 6 399-410.

This is a general resume of the subject with special note on the disease in Recife and a few other towns in São Paulo. The whole is a fair sketch of the

main features of pellagra its history the different theories as to causation its symptoms and pathology, and in general terms the results of treatment by dieting and the giving of nicotinic acid and nicotinamide 1 gm. orally and 3 gm. intramuscularly as a daily dose

In Recife itself during the period 1940-41 there are record of 23 women and 24 men patients. In 34 other towns a total of 94 women and 34 men, altogether 115. The age of one man was not known. Of the others in succeeding decades from the second to the ninth there were 2, 21, 29, 30, 17, 11, 5 and 2, practically half the total in the 30-60-year group. Information obtained by following up the cases (for how long?) showed that of the 68 males 41 had died, 18 were cured, 2 had improved, while 7 were unchanged. Of the 49 females 36 had died and 13 were cured.

II Harold Scott

MAINTNER P. The Pellagra-Electrocardiogram and its Significance. *Acta Med Scandinavica* 1948, Sept. 15 v. 131 No. 3 269-87 3 figs. [31 refs.]

Non-specific changes in the electrocardiogram have been described in pellagra by LACHNILEWITZ and BRAUX (*Brit Heart J* 1945 v. 7 77). The most common are depression of the S-T interval and abnormality of the T wave (T flat, isoelectric, or negative). In the present paper studies are reported on 45 pellagrins. Abnormal or borderline ECG findings were observed in 34 cases; they are thus a common concomitant of pellagra, as frequent as any other single lesion such as dermatitis, diarrhoea or glossitis. The proof that these ECG changes are caused by pellagra rests on the exclusion of other causes and on the response to treatment with nicotinic acid. There was however no relation between the presence or intensity of cardiographic changes and the duration, intensity, or predominant localization of the pellagrous lesions.

In general, a parallelism was found between the course of the disease and of the changes in ECG although there were many exceptions: sometimes the cardiogram became worse during clinical cure and sometimes it improved even when the pellagra ended fatally. In more than half the patients the ECG became normal or improved on treatment with nicotinic acid. In some cases there was further improvement when thiamin or yeast was given as well.

In the discussion it is suggested that failure to respond to treatment may result from irreversible damage to the heart-muscle. Several factors may account for the variability of the ECG changes and the lack of any close correlation with the other manifestations of pellagra. These are variation in the rate of nicotinic acid depletion, and interactions with other vitamin deficiencies, some of which may enhance and others inhibit the process of myocardial damage.

DOXIATES T. & TILIAKOS M. Die Schwarze Zungenzunge (Black Tongue): a) Mangelerscheinung bei Menschen. Black Tongue as a Deficiency Symptom in Man. *Schweiz med Woch* 1944 Oct 23 78 No 4 1011-7 3 figs. 1 ref.

Black tongue of dogs—the analogue of human pellagra—was not seen in human pellagrins but the so-called hairy tongue occur with or without the usual signs of pellagra. The author record four cases. In this condition three recovered on being given nicotinic acid, the fourth, who suffered from diplegia and pernicious anaemia as well as hairy tongue, did not. The author argues that in favour of there being some connexion between the hairy tongue and pellagra in man and the black tongue of dogs are the fact that in the cases here recorded good result followed the administration of

nicotinamide plus vitamin B complex, that in all there was a basal B-avitaminosis, and that the condition developed in the spring. On the other hand, it is acknowledged that up to the present black tongue has not been observed in pellagra nor in times of epidemics, nor has it been produced in experimental pellagra in man, and that it was not recorded in the severe hunger epidemic of 1941-42 in Greece. He concludes with the remark that distinction must be made between acute and chronic deficiency and that it is in the latter that "black tongue" occurs.

HAEMATOLOGY

SCHWEIGERT, B S with the technical assistance of Frances PANZER & Patricia SPARKS. Folic Acid Metabolism Studies. III Intravenous Administration of Pteroylglutamic Acid and Pteroyltriglutamic Acid. *J Lab & Clin Med* 1948, Oct v 33, No 10, 1271-5, 2 figs [14 refs]

BERK, L, BAUER, J L & CASTLE, W B. Folic Acid. A Report of 12 Patients treated with Synthetic Pteroylglutamic Acid with comments on the Pertinent Literature. *South African Med J* 1948, Oct 9, v 22, No 19, 604-11, 7 figs [21 refs]

Twelve cases of pernicious anaemia have been treated with synthetic pteroylglutamic acid in Boston, Mass. The plan of dosage was 10 mgm intramuscularly daily during the initial stages of the response, during which time the diet was devoid of haematopoietically active substances. This was followed by maintenance with 75 mgm intramuscularly once a week. The reticulocyte responses and initial rises in red cell count and haemoglobin were entirely comparable with those seen with purified liver extract therapy. Four patients were studied during ten days to two months of therapy. In three, treatment was continued and complete remission observed. Four showed failure of the blood values to return to normal, this was attributable in two cases to inadequate amount of therapy, and in another to concomitant iron deficiency. Two patients on constant folic acid dosage showed a decline below normal in their blood values after a normal status had been maintained for four and five months respectively. In both, normal blood values were restored by intramuscular injections of purified liver extract.

Neurological manifestations developed for the first time or progressed in one of the five treated with 75 mgm of folic acid intramuscularly weekly from eight to 17 months, but also in two others who had received 50 mgm of folic acid daily by mouth for 6-11 months respectively.

The haematological responses and prompt general clinical improvement following the use of folic acid in pernicious anaemia and related macrocytic anaemias closely resemble the results of liver extract therapy. In some patients, however, development of glossitis and failure to maintain a normal blood picture have been observed under folic acid therapy. In view of the considerable incidence of neurological manifestations in cases of pernicious anaemia maintained on it, folic acid should probably not be used therapeutically in this condition until the nature of this undesirable effect is better known.

DERMATOLOGY AND FUNGUS DISEASES

LEON, L. A. El carate o mal del Pinto en los niños. [Mal del Pinto in Children.] Publicaciones del Ministerio de Previsión Social Quito Ecuador 1944 27 pp. 8 figs. [13 refs.]

This brochure was presented at a Medical Congress held in Quito Ecuador in 1942, was published two years later but was not received here until October 1948. The information it contains was well up to date at the time but contains little that is not common knowledge now. Pinto in Ecuador at least, is far more common in children than is generally believed. In the State of Guerrero of 1,535 patients 633 (47 per cent.) were under 10 years of age. HENRIJON recorded 259 of 683 (37 per cent.) from various Mexican States and the present author found 35 out of 100 cases in Los Chillos Valley to be in children under 10 years. It is estimated that more than half (53 per cent.) of the patients are below 15 years of age. The causes for this preponderance among the young are stated to be first, that the children are out in the field and are attacked by flies and mosquitoes; second, that their skin is delicate and largely unprotected especially the arms and legs; third that they suffer from small lesions scratches erosions and the like; and, fourth that they are the chief victims of other dermatoses scabies impetigo etc.

The author gives the geographical distribution of the disease in Inter tropical America. The chief endemic zones are in Mexico Colombia Venezuela Ecuador Brazil Peru and Porto Rico but cases are also met with in El Salvador Guatemala Honduras Panama Bolivia and Argentina. In Ecuador itself there are four pinto-genic zones: (1) The valley of Los Chillos in the province of Pichincha; (2) the valley of Catamayo, Loja province; (3) Santa Rosa de Machala, El Oro province; and (4) several local in the province of Napo-Pastaza. In six other provinces namely Santiago-Zamora Esmeraldas Manabí, Los Ríos Tungurahua and Azuay, cases have been seen.

The remainder of the article is concerned with the aetiology, symptomatology, course, pathological anatomy, diagnosis, prognosis, treatment both curative and prophylactic, and does not call for detailed notice here. H. Harold Scott

SALVIX, S. B. & HOTTEL, G. V. Serologic Studies on Antigens from *Histoplasma capsulatum* Darling. *J Immunology* 1948 Sept. v (6) No. 1 57-64 3 figs. [23 refs.]

To determine the best antigenic preparation for the detection of antibodies to *Histoplasma capsulatum* in serum, by the complement fixation and precipitation tests the authors investigated seven different *H. capsulatum* antigen

preparations, using the sera of experimentally infected rabbits. The antigens used were (1) A suspension of intact, formalized yeast-form cells, (2) the filtrate of liquid obtained by grinding up a mass of washed, yeast-form cells, (3) the solid residue left after filtration for 2, (4) the filtrate of a broth culture in the yeast form, (5) the filtrate from grinding up a mycelial mat in saline, (6) the solid residue left from filtration for 5, (7) the filtrate of a broth culture in the mycelial form. It will be noticed that 2, 4, 5 and 7 are soluble antigens and 1, 3 and 6 are particulate. Numbers 1, 2, 3 and 4 are derived from the yeast form of the fungus and 5, 6 and 7 from the mycelial form. All seven antigens were immunologically similar, but the particulate preparations seemed to contain at least one antigenic factor not present in the filtrates, a difference demonstrable by antibody absorption.

Precipitation tests with the four soluble antigens gave positive results with rabbit sera drawn up to about six weeks after infection, and reactions at the highest titres occurred with sera drawn when the animals were clinically ill. The strongest reactions were given with the mycelial broth culture filtrate (No 7). These tests gave negative results with sera drawn 8 to 10 weeks after infection. On the other hand, complement-fixation tests with the particulate yeast antigen (No 1) gave the strongest reactions with sera drawn five weeks after infection, but the reaction persisted at a lower titre for at least six months, which demonstrates the value of this test in the diagnosis of chronic infection.

NEGRONI P, DAGLIO, C A N & BRIZ DE NEGRONI, C. Estudios sobre el "Coccidioides immitis" Rixford y Gilchrist V [Studies on *Coccidioides immitis*] *Prensa Méd Argentina* 1948, Aug 20, v 35, No 34, 1652

After a case of generalized coccidioidomycosis had been reported in the Río Colorado area (Río Negro Territory, Argentina) a survey was made to ascertain the probable incidence of the disease in the country.

Intradermal tests with 1/100 standard coccidioidin were made on 2,065 primary school children, boys and girls, between the ages of 6 and 15, in 7 stated areas. Complete results were available in 1,834 children and are shown as percentage findings of positive and doubtful reactions. [It is stated that results were read after 24 hours, but what was the criterion of a "doubtful" reaction is not stated.]

The positive results varied from 1 to 10.26 per cent and the "doubtful" from 1.66 to 5.63 per cent. The high positive figure of 10.26 per cent was found in the Río Colorado area. The highest "doubtful" result (5.63) was in Neuquén. It is noted that most of the positive reactions in the Río Colorado area were ++ or +++ and that a symptomatic case was seen. No correlation was noted between positive findings and sex, but there was a peak of incidence between the ages of 10 and 11.

It is added that one member of the Commission developed a positive coccidioidin reaction and mild bronchitis 15 days after his arrival in Río Negro, which is taken to confirm the "endemic character of the zone investigated." This zone corresponded to the dry regions and the authors recommend soil irrigation as one means of limiting the dangers of endemic coccidioidomycosis.

GUNCHE, F F, RADICE, J C & FEOLI, L S J. Blastomycosis primitiva de boca (Paracoccidioides brasiliensis) [Buccal Blastomycosis (*Paracoccidioides brasiliensis*)] *Semana Méd* 1948, Oct 21, v 55, No 43, 866-9, 7 figs

Report of a case

QUIROGA M I, NEGROSI P & CORPORA L A. Resultado de la terapia sulfamidica asociada a la vacunoterapia especifica en cuatro nuevas observaciones de blastomycosis sudamericana. [Results of Sulphonamide Therapy associated with Specific Vaccine-therapy in Four New Observations of South American Blastomycosis.] *Rev. Argentina Dermatofisiologia* 1947 July-Dec. v 31 Nos. 3 & 568-72, 4 figs. (23 refs.)

The South American type of Blastomycosis (paracoccidioidal granuloma) was formerly believed to be incurable but encouraging results from the treatment of the disease with the sulphonamides have been reported recently.

The present paper records the clinical cure of four cases by means of the combined treatment with intravenous injections of "solithiazamida" a preparation of sulphathiazole 1 gm. daily with weekly intramuscular sulphathiazole 3 gm. daily and a vaccine of *Paracoccidioides brasiliensis* given subcutaneously in increasing doses. Supplementary treatment took the form of intramuscular injections of liver extract and vitamins B and C and local medication of the lesions with sulphonamide pomade alternation with sulphathiazole powder. The first patient an Argentinian journalist aged 53 who had mucocutaneous lesions in the mouth and nose and other ulcerating lesions on the cheek and heel with associated lymphadenopathy as well as evidences of involvement of the lungs, was clinically cured in three months during which time he received 71 injections of "solithiazamida" 231 gm. of sulphathiazole 20 injections of *Paracoccidioides* vaccine and some blood transfusions. The other three patients all males, aged 45, 57 and 47 years respectively received the same kind of treatment and showed similar rapid recoveries. It is noteworthy that one of the three was a syphilitic who had been under treatment for this disease with arsenic and bismuth and had received 3 million units of penicillin with little apparent effect on the blastomycotic lesions.

Brief clinical descriptions of all the cases are given and the authors mention the use of the coccidioidin skin sensitivity test in one case with a positive result presumably paracoccidioidin was meant.

An interesting observation was the apparently long incubation periods of 22 years and 28 years respectively in two of the cases as judged by the interval between the presumed time of exposure to infection and the discovery of mucocutaneous lesions.

LADELL, W. S. S. The Measurement of Chloride Losses in the Sweat. *J. Physiology* 1948 Sept. 30 v 107 No. 4 495-71 7 figs. (15 refs.)

This paper reports the results of direct measurement of salt losses during exercise in hot environments and compares these with the losses calculated from the chloride samples obtained over the same period from the whole arm. Sixteen experiments were done on seven subjects.

The classical studies of salt loss during sweating were based on the recovery of all the sweat produced. That method though accurate is cumbersome and not generally applicable. It has been reported earlier by other workers that the chloride content of the sweat varies according to the part of the body from which it comes. The present results show that in humid heat if the whole arm is enclosed the sweat collected from the arm has the same chloride content as the mixture of sweats from all parts of the body. It is concluded that this finding does not indicate that the chloride concentration in sweat is the same

for all parts of the body, but is probably a chance effect due to the difference in concentration of sweat from different parts of the arm and hand, and to the modifying effect of total enclosure

Although the experiments were only carried out in hot humid climates, it is thought that sweat samples from enclosed arms are equally good as an indication of the whole body sweat in hot dry environments *Thomas Bedford*

MISCELLANEOUS DISEASES

RAPER, A B **Pigmentation of the Tongue** *East African Med J* 1948, June, v 25, No 6, 245-50 [10 refs]

Pigmentation of the tongue is very common in the African. It takes several forms. Most commonly there are brown or inky-blue spots, formed by deposits of pigment in the fungiform papillae. Sometimes these are accompanied by diffusely pigmented plaques, which are brown, slaty-grey, or lilac-coloured. Tongues with inky-blue spots, and those with diffuse lilac pigmentation are grouped together as "blue" tongues.

Microscopic examination showed that the pigment in all cases was melanin, no iron-containing pigment was found. The melanin was located in chromophore cells lying in the corium, just beneath the epidermis. Only a few such cells were found in the deeper layers of the dermis. In two cases with diffuse lilac pigmentation there were widely dilated capillaries in the dermis, with branches running up into the cores of the fungiform papillae. This recalled the capillary dilatation found in the tongue in arriboflavinosis, and in experimental black-tongue in dogs. It therefore seemed probable that blueness was caused by capillary dilatation and stasis. To test this, "blue" tongues were compressed with a glass slide, whereupon the blue colour disappeared. Compression of brown or slaty-grey tongues caused no change of colour.

The remainder of the paper is concerned with the significance of pigmentation in the tongue. From an earlier survey of African soldiers it was concluded that pigmentation, and particularly blue pigmentation, was definitely related to malnutrition. This theory has been tested by a further survey of 500 African labourers. The nutritional status was estimated clinically, and the subjects classed in 3 groups—satisfactory, poor, and bad. The overall incidence of pigmented tongues was 42 per cent, and of "blue" tongues 10 per cent. The incidence was the same in all three groups. The original theory of a relation to malnutrition was therefore not confirmed. Only the minority of cases with capillary dilatation can justifiably be attributed to dietary deficiency.

The author believes that pigmentation of the tongue is related not to nutrition but to skin colour. This could not be tested in the survey, because the subjects had rather uniformly dark skins. He discusses, but dismisses, the possibility of a relation to Addison's disease, and points out how little is known about the physiology of pigmentation in general. In the African, pigment may be found not only in the skin and mucosae, but also in deep-seated membranes, such as the arachnoid and the epithelium of the gut. *J C Waterlow*

LOPEZ BUSTOS, C. Posibles interpretaciones bioquímicas del latirismo [The Possible Biochemical Causes of Lathyrism] *Rev Sanidad e Hig Publica* Madrid 1946, Oct, v 20, No 10, 1027-45 [35 refs]

The author has done much work on the chemical analysis of the vetches—the proteins, prolamines, albumins, globulins, glutelins, the nucleic acids, the phosphatids, lecithins, the starch, amylose and amylopectin, and the

colouring matter. Minute details of these analyses and the results are presented in this paper. Those interested must consult the original, for there are too detailed for reference here.

The discussion as to the possible connexion between these findings and the symptoms of lathyrism is largely, if not entirely, hypothetical. It is acknowledged that vegetal phospholipids, though not themselves antineuritic, nevertheless retard the appearance of symptoms of avitaminosis. The author considers the nutritional value of the plant and the pyrimidine bases and lathyrism, quoting many references to the literature. He then proceeds to discuss the soil factor showing that not all vetches are toxic but only (or chiefly) those grown on certain soils particularly those containing selenium and he concludes in these words (translated). "We do not think that lathyrism is due to deficiency of amino-acids although the proteins of the flour are poor in sulphurated amino-acids. The cause of lathyrism may be the toxic action of nucleic acid or the products of their hydrolysis while the colouring matter may have a harmful action. There is also the possibility that the toxic symptoms may be due to selenium in combinations analogous to the sulphur of the sulphurated amino-acids." *H. Harold Scott*

MAKARI J. G. Serial Cephalin Flocculation Curves: their Application in the Study of Tropical Diseases and their relation to a New Resistance Factor. *J. Trop. Med. & Hyg.* 1948 Jan. v 51 No 1 8-20, 5 figs. & 9 graphs. [17 refs.]

This paper discusses in great detail the experimental approach to and application of serial cephalin flocculation curves in health and disease. It deals in particular with the significance claimed for a resistance factor which is discussed at length. To follow the author's arguments on the interpretation of his results, the paper should be consulted in the original.

PROTOZOOLOGY GENERAL

AMARI N. & MIKOL A. Présence de toxoplasmes dans des frottes de conjonctive palpébrale humaine. [Toxoplasma in Smears from the Human Palpebral Conjunctiva. *Bull. Soc. Path. Exot.* 1948, v 41 No. 7, 463-4]

A Persian girl of 9 was referred to the eye clinic in Teheran from the school medical service with a provisional diagnosis of trachoma. The only eye lesion found was a very limited granular conjunctivitis on the upper eyelids.

Conjunctival smears showed the presence of crescent or cigar-shaped elements measuring $4 \times 6\mu$ and $2 \times 4\mu$ isolated or in groups. They were almost entirely free but in one or two cases the parasites were intracellular. The globular nucleus was central or sub-central, and stained deep red (stain used not specified). Most forms showed binary fission. The protozoan was homogeneous and stained deep blue with a red staining space around the nucleus.

The authors consider from these features that the parasite must have been a *Toxoplasma* and this diagnosis was confirmed by Dr DUBRY. Clinically no special features of note were found in the child. Some months before however, she had suffered from a sharp fever attack for a fortnight but this had

resolved spontaneously. No laboratory examinations had been made at that time. All physical, neurological and psychological examinations were completely normal.

The authors conclude that toxoplasmosis may be manifested solely in granulations in the palpebral conjunctiva that, in addition to the recognized clinical forms, it may exist in a latent form causing those harbouring the parasite to continue to be carriers and that the presence of toxoplasmosis in Iran helps to confirm the very wide geographical distribution of the disease.

Espécies neotropicais da família Simuliidae Schiner (Diptera Nematocera) II *Lutzsimulium cruzi*, n gen e n sp e nova concepção da nervação das asas dos Simuliídeos [Tropical Species of Simuliidae II New System for the Wing Venation of Simuliidae, with a Description of *Lutzsimulium cruzi*] *Mem Inst Oswaldo Cruz* 1947, Sept, v 45, No 3, 667-77, 35 figs

The English summary appended to the paper is as follows — "A new system for wing venation of Simuliidae is proposed. *Lutzsimulium cruzi* n, gen and n sp is described based on a single female and its pupal skin."

LAIRD, M. Reactions of Mosquitoes to the Aircraft Environment. Reprinted from *Trans Roy Soc New Zealand* 1948, Apr, v 77, Pt 1, 93-114 [26 refs] Issued separately as Royal New Zealand Air Force Entomological Bulletin No 5

In reviewing the literature on the carriage of insects by aircraft the author found that, so far as mosquitoes were concerned, there was little information on the reactions of these insects to the aircraft environment and on their ability to establish themselves in new surroundings after surviving the journey. In view of the fact that many aircraft, on the way to New Zealand, call at places where they are likely to pick up insect vectors of human diseases, these problems were investigated during 1946 both in aircraft and in the laboratory.

In the main enquiry, *Aedes notoscriptus* was used, but a few males of *Culex pipiens pallens* were taken on board an aircraft in Japan for study during and after the return flight to New Zealand. The various techniques are described and the observations are recorded and discussed. The main reactions to the aircraft environment may be summarized as follows —

Both sexes of *A. notoscriptus* were sluggish in their movements when exposed to reduced air pressures corresponding to altitudes of 10,000 to 30,000 feet and

they rarely made voluntary flights. At pressures corresponding to those prevailing at 30 000 to 40 000 feet the mosquitoes did not fly at all and seldom made voluntary movements.

Movements were sluggish at 10°C. to 1°C. and voluntary flights became fewer as the temperature fell. The mosquitoes appeared as if dead at temperatures below 1°C., and when maintained at 3°C. to 5°C. for long periods. On being restored to normal air pressure and room temperature (15.5°C.) *Aedes notoscriptus* rapidly recovered and within ten minutes behaviour appeared to be normal and voluntary flight was made.

Vibration did not significantly shorten the life of the mosquitoes even when so intense as to prevent them resting for periods as long as twenty-four hours at various air pressures and temperatures. Survival in the aircraft was not reduced provided the mosquitoes were able to feed. Without food, males were able to survive under all conditions in the laboratory for an average period of four days; females lived a little longer under the same conditions.

Both *Aedes notoscriptus* and *C. pipiens pallens* flew about inside their cages in the aircraft in agitated fashion when the motors were opened out just before the take-off; behaviour returned to normal within five minutes after the plane became airborne. A similar increase in activity was observed when coming in to land.

The male *C. pipiens pallens* brought from Japan lived for an average of six weeks at New Zealand winter temperatures and it is likely therefore that introduced exotic mosquitoes could become established in the warmer parts of the country.

From this work it is concluded, among other things, that the best time to use insecticidal spraying on board aircraft is immediately before turning into wind for the take-off run. It is suggested that the routine pyrethrum-based aerosol should be sprayed from an automatic system controlled from the cockpit and that there should be a supplemental, residual DDT treatment of all enclosed spaces in the aircraft. As a further safeguard, a ground organization should be maintained for carrying out insecticidal spraying in incoming planes, and until the spraying routine has been completed all aircraft arriving from overseas should be required to halt at a designated place on the taxiway before being allowed to proceed to the tarmac for disembarkation of passengers and unloading.

H. S. LORAN

HADDON, A. J. The Mosquitoes of Swamba County Uganda. VI. Mosquito Breeding in Plant Axils. *Bull Entom Res* 1949, Aug. 39 Pt. 185-192, 2 text figs. & 16 figs. on 8 pls. (16 refs.)

This is an account of a study of plant axils as breeding places for mosquitoes with special reference to *Aedes simpsoni*, a known vector of yellow fever in Swamba Uganda.

Larvae of twelve species of Culicine mosquitoes were found during the survey and it was established that bananas, plantains, colocasia and pine apple were the principal plants concerned. The total number of axils examined was 34,75 of which 14,047 contained water. Mosquito larvae were found in 6,373, so that the potential foci inhabited amounted to 45 per cent. Of the twelve species of Culicines collected, larvae of *Aedes triseriatus* were most prevalent (10,679) larvae of *Culex quinquefasciatus* numbered 10,004 and there were 3,171 larvae of *U. annulipes* var. *annulipes*. Other species occurred in smaller numbers: only 23 larvae of *Aedes aegypti* were obtained. A survey of twelve types of plant showed that three of them, wild banana from moist mountain slopes, *Pandanus* from Semliki Forest and *Colocasia esculenta* from the mountain yielded no larvae of *Aedes simpsoni* though they harboured huge

numbers of other larvae. This is thought to be merely a reflection of the fact that they grow in environments apparently unsuited to this particular mosquito. All other plants yielded *Aedes simpsoni*, the most important being the colocasia *Xanthosoma sagittifolium*.

A special study was made of the water content of the plant axils, one of the many factors influencing the preference of the mosquitoes for one plant over another. The general conclusion was that in Bwamba the optimum capacity seems to lie between 4 and 8 cc.

A monthly survey of one hundred *X. sagittifolium* was made from March 1942, to February, 1943. Larvae of eight species of Culicines were collected amounting to 7,217 specimens, 5,188 of these were *Aedes simpsoni* (72 per cent) and 1,082 *U. ornata* var. *musarum* (15 per cent). There were only 10 *Aedes aegypti* larvae. During the year the axils dried out once only for a very short period in February, but the larval populations were completely re-established within 10 days of a light shower.

A collection was made of scrapings from 1,000 dry axils, and 4 living larvae were found. These were discarded and the remaining material was placed in bowls of water. By the second and third days, a total of 24 larvae of *Aedes simpsoni* and 7 of *Harpagomyia taeniarostris* had appeared. The material was discarded after a week as there were no further hatchings.

Temperature readings were taken on seven successive days in a *Xanthosoma* axil and in an adjoining Stevenson screen. The temperature in the axil seemed even more equable than that in the screen, the mean minimum and mean maximum in the axil being 17.5° and 24.5°C respectively, and in the screen 18° and 27°C.

A study of the mosquito output from plant axils was made by collecting pupae from 10 *X. sagittifolium* daily for a month. There was a constant output of pupae which were collected on 29 of the 30 days. The number of axils fluctuated between 69 and 74 and altogether 108 pupae were collected of which 95 were *Aedes simpsoni*. From the figures obtained it is estimated that an acre might contain 500 *X. sagittifolium* which could produce 5,000 *Aedes simpsoni* adults per month, 2,000 of which would be females.

Among the factors tending to reduce the output of adult mosquitoes from plant axils are the presence of the predatory larvae of *Eretmopodites*, an excessive growth of protozoa on the larvae and infection with the fungus *Coelomyces*.

The author concludes with a note on some of the common inhabitants of plant axils other than mosquito larvae.

H S Leeson

REEVES, W. C., BROOKMAN, B. & HAMMON, W. MCD. Studies on the Flight Range of certain *Culex* Mosquitoes, using a Fluorescent-Dye Marker, with Notes on *Culiseta* and *Anopheles*. *Mosquito News* 1948, June, v. 8, No. 2, 61-9, 2 figs.

These studies were made in Kern County, California, during 1946 and 1947. The mosquitoes used were *Culex quinquefasciatus* [*fatigans*], *C. tarsalis* and *C. stigmatosoma*. A method of marking was required which would leave the mosquitoes in a condition fit for tests for viruses and for dissection for plasmodia. A fluorescent dye was chosen as the marker and several were tested but on examination of 78,000 field-caught mosquitoes it was found that numerous specimens had natural fluorescent particles on their bodies, though none of these was red. It was therefore decided to use rhodamine-B, which produced a red fluorescence under ultra-violet light. At first, adult mosquitoes were reared from larvae in water which contained small quantities of rhodamine-B but this method was abandoned because of the high mortality of the larvae and the

frequent failure of the dye to carry over into the adult stage. Next, a larva were fed on sugar water containing the dye, and though the red colour was visible and was retained for several days even after death, the difficulty of getting large numbers made this method unsuitable for flight range experiments. The dusting method was finally used and found satisfactory.

The methods of rearing, marking, transporting and releasing the mosquitoes are described in detail. In 1946 of approximately 47,000 marked mosquitoes only 73 were recovered (less than one out of 650 released). In 1947 23,000 were released and only one recovered out of every 720. It was not intended to determine the maximum range of flight, but to estimate the effective flight range which is defined as the maximum distance from its breeding places that a species is able to fly in numbers sufficient to propagate a mosquito-borne disease or to constitute a nuisance.

The results are tabulated and show that in 1946, *C. quinquefasciatus*, *C. litorea* and *C. stigmatosoma* had a flight range of at least 2.5, 0.5 and 1.0 miles respectively. In the 1947 trials, the flight range for *C. tarsalis* was extended to 5 miles.

It is concluded therefore that an extensive breeding place of two of these species of *Culex* located a mile or more outside the boundaries of a controlled area, could serve as an important source of infestation and may even be so in the case of the third species. For under different conditions these mosquitoes may live longer or travel further. At present however the authors recommend a tentative practical limit for control measures of not less than 1½ miles beyond the population to be protected.

Incidental to the main study *Anopheles pseudopunctipennis* f. *novus* and *Culiseta incidens* were recovered up to 0.9 and 0.6 miles respectively.

H. S. LESTON

SMITH E. A. Aerial Spray Operations in Merced County California. *Mosquito News* 1949 Mar., v. 8, No. 1 1-8 4 figs

In a district of two thousand square miles in California three-quarters of the land produces mosquitoes mainly from irrigated pasture and irrigation of a variety of crops. [The reduction and control of the irrigation water is not discussed.] Many species of mosquitoes occur in the area and two species of *Aedes* are very troublesome biting by day and night and having a long range of flight.

Control of these insects has been by spraying from the air. Two aeroplanes have been available. One is a Stearman biplane with a single 450 h.p. engine. It carries a 130-gallon tank of spray liquid which can be discharged through a spray boom with eight nozzles. These can be operated in pairs giving a rate of discharge of 7 to 28 gallons per minute. It is also stated that the discharge can be regulated between a half and ten gallons of liquid per acre. If these figures are correct they appear to imply a very great control of flying speed. The same aeroplane carries a device for producing so-called aerosol mark by discharging an insecticidal solution into the exhaust. The device which is described in detail elsewhere [this Bulletin 1948, 43 1111] permits discharge from the machine of 1.14 gallons per minute. It is possible to change over from spraying to aerosols while in the air. The second machine known as an Aeromac is much smaller carrying only 33 gallon of spray which is discharged under pressure through ten nozzles. The output is regulated by a control of the pressure and can be between half and one gallon per acre.

The only insecticide used was DDT of which several formulations have been tested. All were applied at 0.4 lb. of DDT per acre. Whether this means used on the ground or only estimated from the output and whether the figure is for pure DDT is not clear. The aerosol from the exhaust has been put down at the rate of 0.7 lb. per acre of actual DDT.

It has been found possible to spray in spite of fairly strong wind and even during the heat of the day, and it is said that spraying has killed all larvae and 95 per cent of adult *Aedes*. The droplets are large with a mass median diameter of 150 microns. With the aerosol, the droplets are of a mass median diameter of 50 to 75 microns, and the use of this is only possible in the very early morning before thermal up-currents have been established. The aerosol has given good penetration through trees and tall grasses.

The paper contains a number of details on swathe width and other matters. The ground staff numbered two only, one man to drive the truck and the other to put out signals for the line of flight.

Most spraying was done over flooded pasture so that no serious damage to fish could result. In certain deeper waters, it appeared that the spray killed fish to a considerable extent, but did no ascertainable harm to birds. In one case when 0.8 lb of DDT per acre was discharged there was an immense destruction of insects of many sorts, some of them certainly beneficial.

If the area to be treated is large, spraying from the air is almost the only possible method and is certainly cheaper than anything one can do from the ground. Valuable figures are given about the performance of the two aeroplanes, the costs and the like.

SACKTOR, B., HUTCHINSON, M. & GRANETT, P. Biology of the Lone Star Tick in the Laboratory. *J. Econom. Entom.* 1948, Apr., v. 41, No. 2, 296-301, 2 figs.

A method is described of maintaining a laboratory colony of ticks, which is a modification of one previously used for rearing *Dermacentor andersoni*. The tick used by the present authors was *Amblyomma americanum* and the host animal was a rabbit. Details of the life history as observed in the laboratory are also recorded.

The ticks were kept in five-inch lengths of glass tubing half an inch in diameter. At the top end these tubes were plugged with cotton wool wrapped in cheesecloth and at the bottom end with a prepared cork.

The cork was first bored through the middle and then one end and the sides were covered with 100-mesh wire cloth. The covered cork was inserted a little way into the bottom of the tube and sealed into position with a few drops of paraffin wax. To provide the necessary humidity inside the tube, one end of a cotton wick was fixed to the cork and the other end was placed in distilled water. In the laboratory, the optimum temperature for *A. americanum* was about 30°C and a humidity between 85 and 100 per cent was favourable.

When the ticks were to be transferred from the tubes for feeding on the rabbit, a stream of carbon dioxide was passed through the gauze-covered cork to immobilize them. The cotton wool plug was removed and the ticks were picked out or brushed out into the feeding boxes ("capsules") cemented to the skin of the animal.

A feeding box was made from a metal pill box, 1.75 inch in diameter. A hole 1.25 inch in diameter was cut in the bottom and a piece of chamois cloth with a hole slightly less than this was cemented to the bottom of the tin, this was then cemented to the shaved side of the rabbit. In the lid of the tin two quarter-inch holes were cut, one of which was covered with stainless steel wire gauze (100 mesh) soldered over it. The lid and bottom were sealed with adhesive tape. Ticks to be fed were dropped into the tin through the second hole, which was then closed with adhesive tape. One tin held four male and four female ticks, or fifty nymphs or five hundred larvae. When the various stages were engorged and had dropped from the host they were collected and returned

to the holding tubes where they moulted, or in the case of the females, deposited their eggs.

Two weeks were allowed between ecdysis and feeding. The average time to complete a generation was eighty-one days and the whole life cycle could be obtained in approximately four months.

JENKINS, D. W. Trembleiid Mites affecting Man. I. Bionomics with reference to Epidemiology in the United States. *Amer J Hyg.* 1948 July v 49 No. 1 22-35 7 figs. 11 refs.

Certain phases of the bionomics of the three species of *Eutrombicula* affecting human beings in the United States were studied in relation to epidemiology and control.

The known geographical distribution of *E. alfreddugesi* in the United States extends from New York and Nebraska south to Florida, Texas and California. *E. mason* is now known from the coastal states from Texas to Florida and Massachusetts also in Wisconsin and Minnesota. *E. batatas* is known in the United States only from Florida, Georgia and Alabama. The average lengths of season during which chigger larvae are active in areas throughout the United States are presented.

The known host animals for these chiggers include 83 species of mammals, birds, reptiles and amphibians. One hundred and twenty-three host records are presented based on the determinations of chigger larvae by the author. *E. alfreddugesi* and *E. mason* are found on all four groups of vertebrate hosts, while *E. batatas* is found only on the warm-blooded birds and mammals. The time of engorgement of the larvae on the host varied with the time of year being shortest in July and August.

The various types of habitats of the larvae and other stages are discussed. Comparative population counts varied from 30 to 300 larvae per minute on 5-inch by 8-inch cards. The seasonal variation in population of larvae and adults is discussed. Adults may be of value in reducing the populations of *Aedes* and *Anopheles* mosquitoes by eating their eggs. The reproductive potential of chigger adults is high—up to fifteen eggs per day were observed. A definite biweekly ovulation cycle was discovered. Individual female chiggers have lived over one year and produced offspring throughout the year.

Identification characters of the larvae and field methods of collecting and mounting are presented.

JENKINS, D. W. Trembleiid Mites affecting Man. II. Control of Larval Behavior for Disease Transmission Studies. *Amer J Hyg.* 1948 July v 48 No. 1 36-44 3 figs.

The behaviour of chigger larvae was studied to facilitate studies of transmission of scrub typhus. Reared 2-day-old larvae of *Eutrombicula mason* and *E. alfreddugesi* were used. Activity rates were measured in a glass arena having controlled temperature, relative humidity and light.

Activity of the chiggers was initiated by change in intensity or direction of light, by movement of air of the substrate or of a nearby object. The direction of movement was determined almost entirely by light. The reaction to light was positive if the larvae had been adapted to higher light intensities but was negative if adapted to lower intensities. Larvae moved in the direction of the vector of two light beams. Gravity had no effect in determining the direction of movement, and no negative geotaxis was observed.

The rate of movement was primarily determined by temperature. Movement took place between 7 and 43°C and was most rapid (3 feet per minute) at 43°C. At 35 per cent relative humidity a cold temperature orthokinesis

reaction was observed below 18C and at 85 per cent a high temperature orthokinetic effect was observed above 38C. In the normal range of activity between 18 and 38C, the rate of increase in movement rate per degree C at 35 per cent relative humidity was 1.5 times as great as at 85 per cent. With continued movement at a given temperature above 20C a decrease in movement rate (fatigue) was observed. This was greatest at higher temperatures. The rate of larval movement on the human body was about 2 feet per minute. The intensity of light did not have an effect on the rate of movement except that at very high intensities the movement was slowed down or stopped. Air movement slowed the activity rate, especially if the direction of crawling was toward the source of the air current. Movement was somewhat slower on a rough substrate than on a smooth surface. No difference in the rate of movement was observed between the two species or between reared larvae and those found in the field. The age of the larvae affected the rate of movement only slightly. A diurnal activity rhythm was observed. In the afternoon there was a marked decrease in activity.

Larval movement was stopped by sudden change in direction or intensity of light, by exposure to very bright light, or to very high or low temperature, or strong air currents. Chiggers often stopped movement and rested when fatigued at higher temperatures below the lethal level.

"By manipulating the environmental conditions around chigger larvae it was possible to almost completely control their activity. This should be of value in experimental transmission studies in preventing escape of minute chigger larvae infected with scrub typhus."

LABORATORY PROCEDURES

LEON, L. A. Diagnóstico microscópico de las enfermedades tropicales de América. [Microscopical Diagnosis of Tropical Diseases of America.] Universidad Central Publicaciones de la Facultad de Ciencias Médicas. Quito, Ecuador 1947. No 2, 108 pp. 26 figs.

The task undertaken by the author is a praiseworthy one—to assist and guide the laboratory worker in the diagnosis of disease in America. Though the title would limit the conditions to the tropics, his remarks are not confined to these regions but include any met with there. Thus, the diseases dealt with are divided into 5 groups: (1) Bacterial and Rickettsial diseases—bartonellosis, leprosy and plague; (2) fungal conditions—coccidioidomycosis, blastomycosis, mycetozoa, sporotrichosis, etc.; (3) spirochaetosis—yaws, pinta, relapsing fever, sodoku phagedaena, Weil's disease; (4) protozoal diseases—amoebiasis, the flagellates, malaria, leishmaniasis, Chagas's disease and toxoplasmosis; (5) helminthiasis—15 infestations are considered—filariasis, hookworm, onchocerciasis, schistosomiasis, paragonimiasis and the common nematodes and cestodes.

Each is dealt with under the headings of causal agent, material to be taken for examination, staining methods, what is to be seen under the microscope, sources of error [very important] and other investigations to be made for confirmation.

[The letterpress, instructions and descriptions are good, though there are signs of careless proof-reading, e.g. Cobbold and Cobbild in successive lines, and Buchereria, the illustrations are poor, about one-third of them are mere smudges and convey no information. If these were improved, the value of a good effort would be much enhanced.]

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

AFRICAN AFFAIRS, 1948, Oct., v 47 No 189 222-7 The Liverpool School of Tropical Medicine

The Liverpool School of Tropical Medicine is celebrating its Jubilee. It is just 50 years since the School was founded by a leading Liverpool shipowner Sir Alfred Jones after Joseph Chamberlain's appeal for the study of tropical diseases.

This paper reviews the achievements of the School, particularly in regard to tropical medicine and public health in Africa. It is written primarily for a non-medical public and the story of that great School needs no re-telling for readers of this *Bulletin*. Among other things the paper recalls the Liverpool School's connexion with Sir Ronald Ross, the foundation of the Sir Alfred Jones Laboratory in Freetown, its admirable history and those well-known workers who received their early training there: the expeditions and other scientific work inaugurated; the work of Warrington Locke particularly in connexion with blackwater fever and the chemotherapy of trypanosomiasis; yellow fever control; the work of the School in two wars and especially the contribution to malaria control in Freetown; and the now familiar chemotherapeutic work on Paludrine.

This review of fifty years' progress by the oldest of the three principal centres of Tropical Medicine in Britain underlines alike the great contributions which it has made to tropical medicine and hygiene and the need for continued contributions by all concerned to the many still unsolved medical problems which exist in the tropical field.

KELLAWAY C. H. The Wellcome Research Institution. *Proc Roy Soc Ser B* 1948 Oct. 28 v 135 No. 890 259-70 8 figs. on 4 pls.

The Wellcome Research Institution has a distinguished history: it arose from the business firm founded in London in 1880 by the two young American pharmacists, Sir John Burroughs and Henry S. Wellcome. The name includes the various research branches of the Wellcome Foundation—the Physiological Research Laboratories, the Veterinary Research Station, the Chemical Research Laboratories, the Laboratories of Tropical Medicine, the Museum of Medical Science and the Historical Medical Museum.

The names of the eminent medical and other research workers who have been employed in the Institution are known throughout the world. It would be invidious to select from them, but readers will reserve a special memory for Dr C. M. Wenyon for 29 years Director-in-Chief whose contribution to the *Tropical Diseases Bulletin* has been continuous since the first issue in 1912, up to the time of his death a short time ago.

Dr Kellaway gives an interesting account of the Institution, illustrated by a few striking photographs.

Charles H. Kellaway

HOODLESS D. W. Central Medical School, Suva, Fiji. Prepared for the Medical Department by the Public Relations Office Fiji 1947 4 pp 21 figs.

This interesting account of the Central Medical School, Suva, was written by Dr Hoodless, who was Principal of the School from 1930 to 1946. It does not contain details of course of instruction given, but is rather an informative short history giving the broad outlines of development and scope. It is illustrated by photographs of students and the School buildings.

Since the inception of the School in 1928 up to the year 1946 225 young men have graduated and have gone to practice in the island of the Fijian group—

Fiji, Tonga, Cook, Samoa, Gilbert and Ellice, Solomon and New Hebrides. They are not trained up to the standard required for medical men in Britain, and they practise under supervision, but they are expected to treat competently all the usual diseases and accidents they meet, and to perform emergency operations of any kind if there is no possibility of removing the patient to hospital.

It is all most attractive and interesting and important. The students in the photographs look happy and full of life, but a special commendation must be reserved for the photograph of the first graduates and two of their tutors, in 1888 [See also this *Bulletin*, 1945, v 42, 416] *Charles Wilcocks*

PARRY, H B, TROWELL, H C & BERRY, W T C **Health and Agriculture Human Needs and the Pastoral Economy of Central Africa** Reprinted from *Year Book of Agricultural Co-operation*, 1947 67 pp [Numerous refs]

The paper was written by three men with African experience, two of them medical and one a veterinarian interested in uses of pasture. The matter was discussed at a conference on rural life, and this paper is the result. It deals with health and agriculture in the savannah grasslands of Africa. The central problem is to ensure that agricultural production increases more rapidly than the human population which depends on it. If it does so a better standard of living will have been achieved.

The problem is of concern to the medical man because the ability of the population to do manual work is limited by chronic infections, poor health and bad food. It is with these matters that the medical section of the paper deals, in brief and general terms.

The health problems are discussed in relation to problems of finance and administration, land usage, village life and rural planning. The authors see the great difficulty of rousing the African to work out his own salvation. The paper covers a range of subjects, which are skilfully integrated.

BIocca, E, AGOSTINUCCI, G & BRONZINI, E *Ricerche parassitologiche preliminari sulle feci dei mammiferi del giardino zoologico di Roma* [Parasites among Mammalia in the Zoological Gardens at Rome] *Riv di Parassit* Rome 1948, Sept, v 9, No 3, 169-75 [12 refs] English summary (3 lines)

This is the first of a series of records of parasitological infections of animals in the Rome Zoological Gardens. The object of the examinations was twofold: to determine the general health of the animals as regards the presence of parasites and to discover whether any new parasites could be found. Altogether 244 animals' faeces were examined in the 3 months, February-April 1948: these included 3 Families of Primates, the Pre-simian Lemurs, 7 Families of Carnivora, 9 of Ungulata, 3 of Rodentia, and 1 each of Pinnipedia, Edentata and Marsupialia. The Cercopithecidae harboured most. Of 59 examined, 39 were passing *Amoeba* [the different species were not determined except division into those with an iodine vacuole (*Iodamoeba*) and those without], 16 *Blastocystis* and 15 worms or their ova. *Hymenolepis* ova were found in 2 Cebidae and in these only. *Trichuris* ova were passed by 13 Cercopithecides. A table shows the detailed findings of all the examinations made. Attention may be drawn to the presence of *Amoeba* in 8 out of 9 Suidae, 11 out of 13 Cervidae, 13 out of 26 Antelopidae and 7 out of 21 Bovidae. Except for the Cercopithecids mentioned above, helminthic infestations were rare. No amoebae were seen in any Carnivora.

Summing up the findings amoebae of one kind or other were present in 95 of the 244 (38.9 per cent.) and 65 harboured helminths (26.6 per cent.) [Future papers may reveal details of more interest. These questions have been raised at the Zoological Society of London for many years and among a much larger number of animals.]

H. Harold Scott

BOOK REVIEWS

MAIGRAITH BRON (M.A. D.Phil. B.Sc., Oxford M.B. Adelaide, Professor of Tropical Medicine Liverpool School of Tropical Medicine etc.) *Pathological Processes in Malaria and Blackwater Fever* pp. xi+430, 8 charts, 2 text figs. & 19 coloured figs. on 1 pl. 1948. Oxford Blackwell Scientific Publications Ltd. [35s.]

This is a work for the specialist in the pathology and pathogenesis of malarial infections and it will necessarily occupy a place on the shelves of all medical scientific libraries. It is a mine of information on the subject and it is surprising that so much has been condensed in a comparatively small volume. Any review of the work must, therefore, be a mere sampling of the more important aspects touched upon.

Chapter I commences with very full and accurate descriptions of the clinical signs and symptoms of the various kinds of malaria followed by suggested courses of treatment to cover all types of cases from the simple uncomplicated case to the malignant types of various kinds. There is also an account of the symptoms and treatment of blackwater fever. After this comes an account of the various parasites responsible for human malaria, which calls for no comment and this is followed by a consideration of the physiology of malaria parasites and the mode of action of anti-malarial drugs. In this connection it is pointed out that the action of such drugs *in vivo* and *in vitro* is not always comparable as some of the drugs most active *in vitro* have little effect *in vivo* in the same concentrations.

A natural follow-up to this opening is a consideration of the blood cells. The blood picture is considered from all aspects and there is cited a voluminous literature dealing with anaemia, the preferences of the various species of malaria parasites for mature or immature cells, the changes in the red cell produced by the parasites, phagocytosis of parasites and erythrocytes, and the mechanisms of haemolysis, sedimentation rate, coagulation time etc.

Chapter IV gives an account of the literature on the plasma proteins, blood sugar, cholesterol and phospholipoids in the blood in malaria and blackwater fever as well as of the inorganic constituents and blood pigment.

The general aspects considered up to this point are now followed by more detailed studies of the various organs with regard to clinical evidence of dysfunction and the pathology and pathogenesis of these dysfunctions.

The first organ to be dealt with is the liver. An account is given of the clinical evidence of hepatic dysfunction and there is a detailed consideration of liver function tests as described by various authors. The general conclusion of opinion arrived at as a result of these tests would appear to be that all patients adequately studied show some evidence of hepatic dysfunction.

There now follows one of the most important parts of the book dealing with the actual physical and physiological damage to the liver tissues and with consideration of the mode of causation of these effects. It is pointed out that even gross deviations of function may not always be accompanied by much anatomical change in structure owing to the fact that the changes in function

are reversible, and it is only when their degree becomes so great as to be irreversible that structural cellular changes become visible. The macroscopical changes are first considered, such as the general increase in size of the organ due partly to congestion and partly to hyperplasia of the cellular elements, the dark colour due to deposition of pigment and the change in consistence. The histological changes are then considered in great detail. A general picture is given of some loss of distinctive lobular structure. In conditions of congestion, the central veins and related sinusoids are filled with red cells, many parasitized, whereas in conditions of severe anaemia, the same vessels are dilated and empty. Malarial pigment is abundant in the phagocytic cells lining the sinusoids and these cells are hypertrophied and hyperplastic. The columns of liver cells are widely separated by the dilated sinusoids and all stages of degeneration of the parenchyma cells from mild granular degeneration to complete necrosis may be present. The latter changes are specially evident in the central region of the lobules. The processes of regeneration, cellular infiltration and repair consequent to these changes are then considered. The description so far is of factual findings in the liver and there now follows an important discussion on the pathogenesis of the changes described. In a comparatively short review it is possible to give only the briefest summary of this section and the original must be consulted by advanced workers on malaria.

Stasis and thrombosis due to mechanical obstruction of the capillaries and sinuses by red cells, parasitized or normal, or by other mechanically operating factors, is uncommon. The lesions, therefore, which resemble those found in right heart failure and are caused by anoxia brought about by interference with the return of venous blood from the liver, must have some other cause. The most probable cause may be looked for in active obstruction to the efferent venous flow caused by changes in the venous blood vessels and this may be due to a possible sphincter mechanism in the hepatic veins. The result is a stagnant anoxia similar to that obtaining in heart failure.

Additional factors in bringing about this result might be the hypothetical malarial toxin, by-products of the metabolism of the parasites and, possibly, autoantigenesis of the parenchyma cells. The reason for the central distribution of the lesions in the lobules is not known, but various hypotheses are put forward.

An equally important section deals with the kidney in malaria and blackwater fever. As in the case of the liver, there is first a description of the clinical signs of involvement of the kidneys in all the common forms of malaria. These signs are temporary proteinuria in the acute malarial attack, without involvement of the nephron. More rarely, the nephron may be involved with definite tubular damage but this is more common in the course of chronic, recurrent, or repeated infections, especially in quartan malaria. As regards renal dysfunction in acute malaria and blackwater fever, the evidence is conflicting but there is general agreement on certain points. Thus, acute renal symptoms are commonest in *P. falciparum* infections and vary from simple albuminuria to definite nephritis or nephrosis. Less often the picture simulates an acute streptococcal nephritis with oliguria, uraemia and nitrogen retention, while in recurrent malaria, especially in *P. malariae* infections, the exacerbation of malaria may be accompanied by increase in the existing renal damage leading to death by uraemia.

The pathological changes, both those of a general nature and those specially related to the parenchymatous tissues, are described in acute and chronic malaria and the changes in blackwater fever are separately considered. In the latter case there is general agreement that few changes are found in the glomeruli, most of the damage being confined to the tubules where the epithelium shows degenerative and necrotic lesions and the lumina are plugged with casts.

The chapter dealing with the pathogenesis of the renal lesions is extremely difficult to summarize on account of the number of conflicting theories based largely on animal experiments, and the account should be read in the original. The conclusion is drawn that the pathogenesis of the renal lesions and renal dysfunction in malaria and blackwater fever are essentially identical and not dissimilar to that of syndromes arising in other conditions where there is renal anoxia. The basic aetiological factor is probably anoxia of the renal tissues especially of the cortex and for this the term renal anoxia is proposed. The renal anoxia it is suggested arises from reduced renal blood flow affecting chiefly the cortex and often accompanied by a general peripheral vascular collapse. There is probably in all cases a reduction in total renal blood flow and a redistribution of blood flow in the kidneys resulting in anaemia and consequently anoxia of the cortex.

The brain is the next organ to be dealt with. Clinical manifestations of involvement of the brain have such an immense literature that no attempt is made by the author to deal with them and the reader is referred to the many reviews on the subject. The pathological changes in the brain both macroscopical and histological are described on conventional lines and need not be enlarged on beyond saying that the descriptions relate almost entirely to materials derived from fatal cases of *falciparum* malaria and blackwater fever.

The pathogenesis of the brain lesions is less complicated than that of the liver and kidney lesions. The lesions most consistently present involve the blood vessels capillaries and small arterioles especially those of the white matter. The older view that the vascular damage is due to obstruction of the blood flow in the smaller vessels accompanied by diapedesis of red cells and that degenerative changes in the nervous tissues are the result of deprivation of their blood supply may have to be modified. The latter opinion may still be correct in as much as the condition will necessarily lead to anoxia of the tissues but the cause of the stasis is probably not direct obstruction but concentration of the corpuscles due to loss of fluid from the vessels through damage to their endothelial lining rendering them permeable. The primary cause or causes of these effects are more obscure and are discussed at some length.

The spleen and bone marrow are next dealt with. The naked-eye and histological appearances are described and the pathogenesis of the changes is considered.

The adrenals in malaria are discussed in a short section. Clinical symptoms in some kinds of pernicious malaria are similar to those of adrenal insufficiency to such an extent as to have been remarked upon by many workers. However symptoms closely resembling traumatic shock may sometimes be seen in malaria without obvious adrenal damage and it is difficult to assess accurately the rôle of the adrenals in the pathogenesis of malaria. Clinical evidence is based on the asthenia, lowered arterial pressure and peripheral vascular failure with skin pigmentation abdominal cramps etc., as well as on chemical evidence on the blood and tissues but it has to be noted that conditions such as shock and anoxia which are concomitant of severe malaria may give rise to the same chemical evidences.

The heart in malaria as an organ seldom seriously affected, is dealt with quite shortly and call for no special mention.

The concluding chapter deals with some pathological processes in malaria not covered in the previous chapters. The paroxysm is considered a reaction to a non-specific pyrogenic agent, the precipitating factor being a yet undetermined. Anoxaemia the rôle of haemozoin and circulatory phenomena, are also considered.

The tissue responses are no more than touched upon and this also applies to the question of immunity, natural and acquired

Misprints and such minor blemishes are conspicuous by their rarity and those mentioned here are noted merely for correction in any subsequent edition. Thus, in the description of *P. malariae* on pages 43 and 44, no reference is made to the presence of Ziemann's dots in the cytoplasm of the red cells although the absence of Schuffner's dots and Maurer's dots is mentioned. On page 323 "Paisseau" is wrongly spelt in the last paragraph.

In a book covering so large a field, compilation of published work must form a great part and the sources of information are given in brackets. These brackets become somewhat wearisome in continuous reading although the reviewer can offer no substitute for them and these very references make the work one of great value.

It is a pleasure to record the smooth phraseology and excellent construction of sentences throughout the work, which make for complete clarity in the exposition of the author's views, a merit often lacking in scientific works.

H E Shortt

GIGLIOLI, George [M D It, M R C P Lond, D T M & H Eng, Medical Adviser, B G Sugar Producers' Association, etc] *Malaria, Filariasis and Yellow Fever in British Guiana. Control by Residual D D T Methods with special reference to Progress made in eradicating *A. darlingi* and *Aedes aegypti* from the Settled Coastlands.* With Foreword by F L SOPER, M D pp x+226, 47 figs 1948 Mosquito Control Service, Medical Department, British Guiana

There has been no publication with a more important bearing on the policy of malaria than this since the appearance of SOPER and WILSON's "*Anopheles gambiae* in Brazil, 1930 to 1940" [this *Bulletin*, 1944, v 41, 324]. That account described for the first time how anopheline species could be eradicated from large areas by the time-honoured methods of larval destruction. This is the first really full account of which the reviewer is aware which sets out all the details of anopheline eradication by the new means of destruction of adult mosquitoes with residual insecticides.

Lest too much should be assumed on the transferability of data and conclusions, it is well to emphasize the author's words that today, as in the past, generalizations are not possible *in re malariae*. His findings and conclusions refer exclusively to British Guiana mosquitoes and British Guiana conditions. But with this necessary qualification the work described should set a standard for much else.

British Guiana lies between 1° and 8°N. It has a population of 375,819 souls, of whom 90.5 per cent are concentrated in a narrow coastal belt which is from 2 to 4 miles broad, and where much of the land is at or below sea level and devoted to the farming of sugar cane. The climate is hot and moist throughout the year, the annual rainfall (94 inches) is distributed throughout the year, but mainly occurs in the spring and early summer. Malaria is endemic, normal spleen rates ranging around 40 per cent except in some small favoured areas where they range round 10 per cent. Sixteen species of anophelines are recorded, and of them three may be malaria carriers, *Anopheles darlingi*, *A. aquasalis*, and *A. albivittatus*. The first of these is undoubtedly an important carrier responsible for the transmission of malaria over most of the populated coastal belt, and the other two may have an influence in restricted, less malarious, areas.

A. darlingi is naturally a forest species, artificially encouraged in the open cultivated coast lands where it breeds profusely in the irrigation system, its

associated swamps and in the cultivated fields themselves. The adult is very domestic, shelters exclusively in houses and feeds almost entirely on human blood. The houses are for the most part built of sawn hardwood, sometimes with paper or other decoration.

The potential value of DDT in these conditions was realized in 1944 and the initial experimental work was carried out by SYMES and HADAWAY in 1945 (this Bulletin 1945 v. 42, 785). Since then adult mosquito destruction by DDT has been extended through the entire area of the populated coastal strip under a dual organization in which Government and the planting industry have cooperated.

Most available varieties of material and apparatus have been tried and are reported on. After the initial trials, a 5 per cent. solution of DDT in kerosene was adopted as the standard material. It was applied mainly from stirrup pumps with an improved, locally made nozzle at a dosage which rarely varied greatly from the standard 150 to 160 mgm. per sq. ft. (5.3 to 5.7 ounces per 1,000 sq. ft.) which was considered best suited to local conditions. Observation showed that an interval of 8 to 10 months between sprayings kept up a sufficient lethal effect and a normal period of 3 months was decided on.

The author realizes and emphasizes that the non-absorbent nature of the typical wall surface and the habits of *A. darlingi* were greatly in his favour. Treatment of houses resulted in an immediate great reduction in the numbers of all anopheline species and marked but short-lived reduction in the numbers of *Culex fatigans*. When some but not all, houses were treated anopheline breeding was maintained but when all houses in any one locality were treated, the reduction in *A. darlingi* was so great as to end in a total cessation of breeding though no anti-larval measures had been applied. For instance in one area partial treatment was carried out in 1945 and 1946 in which years 3,270 and 713 potential breeding areas were searched and 71 per cent. and 23 per cent. found positive. In 1947 all houses were treated and all of 867 breeding places searched proved negative. Extension of this principle of complete treatment throughout the coastal belt has resulted in the complete eradication of *A. darlingi* from it.

The eradication of this very dangerous malaria carrier has been achieved by DDT used exclusively as a residual spray applied to the interior of houses completely ignoring all phases of hydrological control. These results are all the more significant as a more hopelessly difficult hydrological situation could hardly be conceived.

The effects on malaria are equally marked but much more delayed in their appearance. There was a steady slow decline in the spleen rate—in a typical example records before and at roughly six-monthly interval after the first application of insecticide were before treatment 71.9 after treatment 48.5 31.0 28.2 17.9 12.2 8.0 4.0. Changes in the parasite rate did not follow this course. In the same example the corresponding parasite rates were before treatment 40.3, after treatment 18.0 30.7 33.3 27.1 41.1 6.9 3.0. On analysis of the slow reduction it is shown that *Plasmodium falciparum* infections rapidly decreased, in most places disappearing within 4 months. *P. vivax* infections persisted longer and *P. malariae* was yet more obstinate. The numbers of parasites of all three species decreased quickly so that a couple of years after the initial treatment few films contained more than two or three rings the species of which was difficult to identify.

The average annual cost for establishing and maintaining control including repeat spraying and all overheads amounted to 5.43 per house or 0.637 per c. pad. As *A. darlingi* persists in the interior forests some large part of this must be considered as a permanently recurring expense.

Filaria, due to *Wuchereria bancrofti* carried by *Culex fatigans* can be shown in about 16 per cent of the population by a single blood film examination. This mosquito is much less susceptible to destruction by DDT than is *A. darlingi*, and cannot be brought under complete control by it unless anti-larval measures are simultaneously practised. The author fears the risk that strains which are highly resistant to DDT may develop. However it is partially susceptible, not only are its numbers greatly decreased but its normal span of life is lessened in a treated area so that mature embryos are rarely seen, and the author is hopeful that transmission of the worm may be greatly impeded. The long life of the parasite in man makes factual observation on this point difficult until a new generation of people brought up under the new conditions can be examined.

British Guiana has suffered from urban yellow fever and is within the endemic area of jungle yellow fever so that *Aedes* control is constantly necessary. In the past this has been carried out in townships by standard measures directed against breeding, by which it had been found possible to secure eradication in any locality in four months at a cost of \$4.18 per house or \$1.39 per head of population. Trial showed that, with DDT residual spray, this result could be achieved in 13 weeks at a cost of \$1.76 per house or \$0.47 per head of population. Re-infestation of breeding places occurred at about 10 months after treatment of houses. In, apparently, townships where regular spraying for the control of malaria is not needed, a combination of adult destruction with sealing of barrels, drums and suchlike breeding places has been adopted as the most economical and effective.

The reviewer has tried to excerpt the outstanding points from a most comprehensive report, omitting reference to dozens of important points which are fully described. Despite the pertinence of the original warning, this is a publication of very wide interest.

G Macdonald

STITT, E. R. [M.D., Ph.D., Sc.D., LL.D., etc.], CLOUGH, Paul W. [M.D., etc.] & BRANHAM, Sara E. [M.D., Ph.D., Sc.D., etc.] & Contributors. **Practical Bacteriology, Hematology, and Parasitology**. Tenth Edition. pp. xiv + 991, 7 coloured pls & numerous text figs. 1948. London. H. K. Lewis & Co. Ltd. [50s.]

Each successive edition, this being the tenth, of this deservedly well-known text book has been a matter of interest and importance to laboratory workers dealing with medical subjects.

This latest edition is under the names of STITT, E. R., CLOUGH, P. W. and BRANHAM, S. E., the last-named being added for the first time, while the name of M. Clough has been dropped. In size, the work has changed little and the format is similar to that of previous editions.

As in previous editions the majority of the illustrations are excellent but there is a considerable number of new figures, not all of which are happily chosen.

The present edition, as the previous one, is divided into four main sections dealing with Bacteriology, Haematology, Parasitology and Clinical and Pathological Examination of Body Fluids and Organs. These sections are followed by an appendix describing various laboratory procedures not previously dealt with in the text. While it is impossible adequately to review a book of this size in a limited space, a short consideration of the various sections is necessary merely to denote their scope and usefulness.

Bacteriology

This is dealt with in 12 chapters, totalling 373 pages which comprise more than a third of the entire book. Most aspects of bacteriology and bacterial

immunity are dealt with and the section also contains chapters on the filtrable viruses and on medical mycology. One might suggest that the latter at least possibly deserved a section to itself. Description and method of identification of bacteria causing disease are described and a number of useful summary tables is included. The spirochaetes, rickettsiae and filtrable viruses are adequately dealt with within the limits of space available but cultivation of the filtrable viruses is given not much more than half a page on pages 17 and 18. Bacteriophage is similarly dealt with in a page and a half and no account is given of its use in typing strains of bacteria. Medical mycology receives somewhat less space than its importance especially in the tropics would warrant but it cannot be said that anything of great importance is omitted. One quite obvious error is the photograph on p. 14 purporting to depict *Leishmania* in heart muscle for comparison with a lesion due to *Trypanosoma capsulatum*. It is clear that the first figure illustrates infection of heart muscle with the *Leishmania* form of *Trypanosoma cruzi* and the mistake is unnecessarily emphasized on page 522 where the identical photograph is correctly given as an illustration of infection with that parasite.

The chapter on immunity and hypersensitiveness contains much in little space and the remaining two chapters describe most of the media and staining methods likely to be used in general laboratories.

In this large section it is inevitable that there should be some error and omissions of which, apart from that already noted one may be mentioned since it occurs in the important table on page 18 listing diseases of animal transmissible to man. Obvious omissions here are leishmaniasis, American trypanosomiasis, balantidiosis and tick borne relapsing fever in all of which the natural reservoirs may be animals.

Haematology

This is a good section. The techniques of blood examinations are described quite fully and there follows a description of the normal and pathological elements of the blood. From this there proceed naturally the description of various blood diseases.

The name of such a well-known fauna Mayer haemaphysom (wrongly) felt Meyer on page 329.

Parasitology

This is one of the major sections and is divided into part dealing with Protozoology, Helminthology and Entomology. The first part of the section deal with Medical Protozoology and commences with a table of protozoa causing specific human diseases. This seems fairly complete but *Toxoplasma* is omitted although on page 535 it is referred to as a protozoan (sic). On the other hand *Plasmodium knowlesi* is included although the fact that it is inoculable to man does not make it a protozoan causing a specific human disease.

On page 488 again *P. knowlesi* is listed as a cause of disease in man and in the same connexion the name of such a well known worker in malaria, Sinton is wrongly spelt. In the same small list the equally well-known Stephen is also wrongly spelt.

On page 494 in talking of the gametocytes of malaria the statement "the gametocytes do not produce symptoms and disappear if not picked up by the appropriate mosquito" The meaning of this is quite obscure. On page 495 in describing the reason for the commonly applied titles benign tertian, malignant tertian and quartan the reason given for the first of these titles is "because the untreated infection usually terminates in a few days or weeks without serious effects on the host." In view of the notorious tendency

of this parasite to resist cure even when the natural defences of the body are aided by anti malarial drugs, this statement is difficult to accept

The section on diagnosis of malaria in man, page 497, gives one the impression of an armchair approach to a practical problem. In practice, if thin and thick films were consistently negative, is it probable that recourse would be had to inoculation of blood into a susceptible person or to sternal puncture even if the latter, as suggested, should replace "the hazardous splenic puncture?" Also, on page 502 under the heading of *Plasmodium knowlesi* what is the meaning of the words "while this parasite is not likely to be encountered without previous knowledge of the species involved"? It is not a knowledge of the species which would prevent it being encountered but the fact that it is not a human species. The section on malaria, apart from such small but irritating inaccuracies, is not among the best in a work where such high standards have been maintained in the past.

The blood flagellates occupy 12 pages, of which the space of 4 pages is taken up by illustrations. As regards culture media, NNN medium is dismissed after mere mention, although it is the standard method used in many countries. This is a pity as it is so easy to prepare and so generally useful. In dealing with diagnosis, the complement fixation test for kala azar, involving the use of acid-fast organisms in preparing an antigen, is not discussed specifically although it has been so favourably reported on in India.

The intestinal protozoa are adequately dealt with but one would have expected more information than is given on the gross and microscopical appearances in liver abscess due to *E. histolytica*.

The chapters on helminthology give a good account of all the parasites likely to be encountered in man and most of the information a medical officer in the tropics might require is to be found in the 96 pages devoted to this section. There are some minor errors such as on page 596 where *Loa loa* (Cobbold 1864) Castellani and Chalmers, 1913, is obviously wrong as regards the second date. *Entomology*

This is a small section of only 60 pages. Scrub typhus, which was an important war disease in the Far East and Pacific war areas, is dismissed in 12 lines on page 177 and the vectors in 6 lines on page 662. The space given to the vectors is less than that allotted to butterflies and moths.

In dealing with the genus *Phlebotomus*, some of the vectors of kala azar in the Mediterranean area and in China are given as though they were proven without doubt.

The mosquitoes are hardly given the space their world-wide importance would appear to earn and the two pictorial keys to adults and larvae, refer only to species found in the United States.

Part IV of 176 pages is one of the main sections of the work. It describes all the clinical and pathological examinations likely to be required in respect of body fluids and organs. The section is excellent and it is not necessary to pick out particular details.

The index is disappointing. There is no mention in the index of the mouse protection test in yellow fever although it is described in the text. Similarly "sternal puncture" is not mentioned in these words although described in the text.

Tissue culture is looked for in vain in the index and the same applies to splenic puncture the technique of which does not appear to be described. Many other instances could be cited of facts presented in the text but which it would be difficult to locate by the index.

So far it is chiefly defects and omissions which have been pointed out in order that they may be remedied in the next edition. This has always been, and still is, so useful a book that the issue of further editions is assured.

The scope of the work is so wide that one is tempted to find so few of the real essentials omitted and the book can be confidently recommended to workers in laboratories where an extensive library does not exist and especially to those who may wish to have only one omnibus work to carry all in it.
H. E. SALT

BREED Robert S. [New York State Experiment Station (Cornell University) Geneva New York] MURRAY E. G. D. [McGill University Montreal Quebec Canada] & HITCHENS A. Parker [University of Pennsylvania Philadelphia, Penn.]. *Bergey's Manual of Determinative Bacteriology*. Sixth Edition pp. xvi+1529 1948. London Baillière Tindall & Cox, 7 & 8 Henrietta Street W.C.2. [82s. 6d.] [Review appears also in *Bulletin of Hygiene*]

The new edition of this work is an imposing manual. It is over 1400 pages long and contains an enormous amount of information—descriptions of 30 new species are included. A saving of space has been effected by using double columns for each page and the result is very pleasing. A further innovation is the inclusion of an index giving the source and habitat of different bacteria. This should be extremely useful. It must have taken a lot of time and labour to compile and it is natural that some inconsistencies should have occurred. For instance twelve organisms are listed under "Conjunctivitis" but only three under the "Eye" six organisms are listed under "Arthritis" but only two under "Joints" and so on. The book as a whole though bulky is well produced—it opens flat at any part and the pages do not stick together—it is admirable therefore for reference work and is a credit to both the authors and the publishers.

Most students of bacteriology are already well acquainted with the principles and subject matter of the book, and there will be no need to remind them of the extent to which the authors for the sake of taxonomic completeness have carried the classification and nomenclature of micro-organisms. Not only the true bacteria about which we still know far too little are neatly described, but even the bacteriophages and filtrable viruses whose very nature is in doubt, are duly provided with their names and ranks. Serious writers are therefore asked to refer to a staphylococcal phage as *Phage aureus* to the lymphogranuloma virus as *Mycogranuloma lymphogranulomatis* to the foot-and-mouth virus as *Hoeds pecoris* to the mumps virus as *Rubella infantum* and to the yellow fever virus as *Charon erugatus*.

The old die-hard breed of bacteriologists who would admit no generic extensions beyond *Bacillus*, *Streptococcus*, *Staphylococcus* and *Mycobacterium* have undoubtedly lost the day and good terms such as *Brucella*, *Chlamydia* and *Salmonella* have come to stay—but it may be doubted whether it is wise to pursue the road to classificatory completeness as far as the present authors have done. As a concordance to the book of descriptive bacteriology *Bergey's Manual* is indispensable. As a guide to taxonomy and nomenclature it alone may perhaps be doubted.
C. A. HADSON

GHOSH Barendra Nath (F.R.F.P. & S. (Calcutta) F.R.S. (Lond.) etc.) *A Treatise on Hygiene and Public Health with special reference to the Tropics*. 12th Edition pp. xvi+764 153 figs. 1948. Calcutta New Publishing Co. [Rs 15 or 22s. 6d.] [Review appears also in *Bulletin of Hygiene*]

Yet another edition of this excellent work has appeared within the year of the preceding and it bears all the signs of very careful revision and unremitting energy in bringing the information up to date in climatology

redundancies and in re-writing whole sections instead of merely patching. To speak of general matters first. The whole format has been changed, recast. The print is larger and clearer, nevertheless by judicious elision of what is, or what has in the course of time become, redundant, by placing subjects of subsidiary importance formerly in large print into small print, in spite of many additions—and these are to be found in every chapter—the author has not materially increased the size of the book, it is only 54 pages longer than the last edition. Ten redundant figures have been omitted, five new ones appear and another, the Normal or Probability Curve, is given in a new and better form. It is a pity (this may be purely a personal view) that the illustration of the artificial cooling of a room has been dropped. An error in the numbering of figures has crept in, those on pp 307 and 352 are both numbered Fig 64, and those on pp 366 and 379 both Fig 68. The titles of two chapters have been changed. Chapter 23, Restraint of Infection becomes Control of Infection, and Chapter 28, Vital Statistics is enlarged to Statistics and Statistical Methods. Though it is essentially a "one-man book", the author has availed himself of a judicious choice of helpers whose share is generously acknowledged. Proof reading has been carefully done, misprints are few, only a dozen have been noticed in the whole work of over 700 pages.

So much for general points, we pass on to some in more detail. The Introductory chapter on Preventive Medicine and Public Health Administration is nearly double the length of that of the 11th edition and is a great improvement. Chapter I on the routine bacteriological examination of water is now in small print. Chapter II has additional sections on Air Disinfection and on War Gases, and that dealing with the amount of air required for ventilation has been rewritten. Some additions have been made on examination of the ventilation of a room, and on p 97 estimation of hydrogen by katharometer is mentioned, but the instrument is not described. Into Chapter III on Occupational Hygiene there have been several subjects introduced, notably improvements in the status and welfare of the industrial worker, his housing and nutrition, maternity benefits, the establishment of crèches and first-aid posts. The dangers of manganese poisoning, omitted in previous editions, are now dealt with. This chapter will in the future assume even more importance when the papers (more than 200) presented to the recent International Congress on Industrial Medicine held in London last September are published.

Chapters IV and V, on Soil and Housing, have been revised and sections previously in large print are now relegated to small. Chapters VI-X on Food have been added to and amplified, especially the sections dealing with vitamins and food preservation. Fish poisoning deserves more than the cursory mention accorded to it in 11 lines. Much of what was written on Eugenics in the preceding edition in chapter XV devoted to Personal Hygiene has wisely been omitted in the new issue, notably the summary of the policy of the British Eugenics Society. No mention is made of dhobie itch, a troublesome condition in the tropics, or of its varieties about which a good deal has been written in late years. Chapter XVIII, on Maternity and Child Welfare, still retains the figures of ten and more years ago. It should be possible to obtain more recent data on infant mortality in England and Wales than those of 1938, those in Madras city in 1932, and in Calcutta and Bombay in 1937 and 1938 respectively.

In Chapter XXI, Infection and Carriers of Infection, space has been saved by substituting small print for the section describing types of infecting organisms and a section dealing with escape of organisms from the respiratory, intestinal and urinary tracts has been inserted. The incubation period of whooping cough has been changed from 4 to 14 days to 7-14 days. This is known to be variable but the limits are thought to be wider than these, 3 days

to 3 weeks has been claimed. The diction on p. 401 is a little doubtful. We must repeat regarding chapter XVII the same criticism which was made on the previous edition that without indication of the magnification of figures for merely measurements stated in the text the relative sizes of helminths depicted are liable to mislead—for example on p. 44 *Gastrodiscoides hominis* will appear to have four or five times the bulk of *Fasciolopsis buski*.

Chapter XVII is one of the most important in the book dealing with Epidemiology and Preventable Diseases. Incorporation of Shortt and Garnham's work on the exo-erythrocytic stage of the malaria parasite (not published until March 1948) indicates how closely to date the author has brought his observations. Inclusion of remarks on Gamexane is further evidence of this as is the inclusion of a recent graph of cholera mortality in Bombay in 1945-48. No mention is to be found of the annular erythematous rash of African trypanosomiasis and the American form is still wrongly called Chagas disease. *Nosoprylus fasciatus* is given its discarded name *Ceratophyllus*. The use of live vaccine in plague prophylaxis is introduced. The statement repeated in former editions, of second attacks of yellow fever has been expunged but on the other hand not many who have lived and worked in countries where enteric fever is common will agree that "relative immunity lasts for a long time frequently for life." Sir Almroth Wright's figures of the results of TAB inoculation in the First World War are given but none more recent. In view of the large epidemics of alastrim which may occur and in fact have occurred this type of smallpox deserves more than transitory mention in a couple of lines. The introductory section on Dietetic Diseases is good and new. One still looks in vain for remarks on infantile beriberi and Dr Fehly's work in connexion therewith. The rabies section is confused—remarks on the virus actually refer to the Negri body and not to the filtrable virus and mention we think should be made that the more acute and more rapidly fatal the disease the smaller are the Negri bodies and consequently the harder to find and the greater likelihood of their being missed. The explanation accounting for the variability of incubation period of rabies need amplification. The account of leprosy has been practically rewritten and brought up to date especially that part which deals with control and prevention. Finally a third appendix has been added the P.H. (Aircraft) Regulations 1938, in conformity with the International Sanitary Convention for Aerial Navigation.

The above criticisms are not made in any carping spirit but as suggestions for the author's consideration. The book remains one of the best work on Public Health known to the reviewer and the author is to be most heartily congratulated on the success of his efforts. H. H. Gold Scott

The Nomenclature of Disease drawn up by a Joint Committee appointed by the Royal College of Physicians of London. 7th Edition (being the 6th revision subject to Decennial Revision) pp. xiii 384 1944 London H.M. Stationery Office. [8s. 6d.] (Review appears also in *Bulletin of Hygiene*.)

Since the sixth edition of this work was published 17 years ago, numbers of classifications of disease have been produced in Britain and the United States. These have embodied statistical indices and it is recognized that while statistical classification and a nomenclature are common ends, they should not be confused. In the introduction the distinction made between classification from authoritative sources and it is emphasized that the S.I. Committee

charged by the Royal College of Physicians of London in 1944 with the compilation of the present work "has been solely concerned with providing a Nomenclature of Disease, though it has designed its classifications to serve as a basis for a statistical code" The list of members of the Committee and Sub-Committee is an impressive one, occupying three pages, and it is evident from the names that no pains were spared to obtain the most expert advice available in the preparation of each of the many sub divisions of the subject matter That it should be nearly five years since the work was begun makes it inevitable that a great deal of the results of medical research, especially during wartime, should not be revealed in these pages This is a failing which can hardly be overcome, particularly at the moment when publishing difficulties are manifold, since a task so vast and ever expanding must need revision almost as soon as it has been completed, if it is to be up to date Nevertheless, the Nomenclature is as up to date as it could possibly be made and the time which it has taken to compile is also evidence of the immense amount of care and labour which has gone into its preparation

The volume opens with an aetiological classification of disease, under such general headings as mechanical, structural, functional, metabolic and pre-natal influences There then follow the aetiological agents in diseases due to plant and animal parasites The diseases themselves are first named alphabetically and lists of pathogenic bacteria, spirochaetes, rickettsiae, viruses and fungi follow These in turn, are followed by lists of protozoa, helminths and arthropods, with the diseases caused or carried by them and their habitat, where this can be defined An excellent feature is a list of diseases carried by arthropods, with full lists of vector species There then follows the aetiology of diseases due to intoxication, physical agents, circulatory, blood, nervous and undetermined causes

The second part of the book gives a systematic list of diseases on a regional basis and this occupies over two-thirds of the volume

A feature of particular value is the appended list of eponyms, which occupies some 14 pages and includes a large number of diseases commonly having eponymic descriptions, with their scientific definitions attached Two final pages in this list include diseases named after locality and occupation the former is perhaps of questionable value, since the number of geographical and topographical attributes given to many diseases is very large, and the inclusion of some, but not all, of the well-known names is, perhaps, apt to be confusing For example, cutaneous leishmaniasis is given as the definition of Baghdad Sore, Delhi Sore, Lahore Sore, Oriental Sore and Natal Boil while Aleppo Boil and Biskra Button are shown as Baghdad Sore A number of geographical names, besides the more familiar ones, are given for brucellosis and Hong Kong ear is defined as aural aspergillosis [though in the reviewer's experience, a common tropical ear infection in which *Ps. pyocyanea* is prominent has been named in turn after most of the better-known tropical cities] Egyptian splenomegaly is defined as Kala Azar, though it should perhaps correctly be reserved for a feature of schistosomiasis

These very minor criticisms among tens of thousands of entries will be regarded, it is hoped, as evidence not of defects in the work, but of its outstanding lack of them This Nomenclature is monumental in scope and presentation alike because of the immense amount of practical and definitive information which it contains, it should never be outside easy reach of any medical workers' hand, for without it, it would be difficult for him indeed to maintain in his writings such a standard of wide and accurate definition as medical activity demands and the present compilers have achieved

H J O'D Burke-Gaffney

NEW YORK STATE DEPT OF HEALTH Laboratory Manual for Physicians Aids in Diagnosis and Treatment. Ninth Edition pp vii+129 8 in. 1948. Issued by Division of Laboratories and Research Albany. [Review appears also in *Bulletin of Hygiene*]

The staff of the Division of Laboratories and Research, New York State Department of Health are in a position to speak with a considerable weight of authority on laboratory services since for example in the year 1947 alone the total number of tests performed in their laboratories amounted to more than six million.

The need for and value of a Manual of this nature are made clear in the

the New York State Association of Public Health Laboratories maintain a standing Committee on the use of laboratory facilities and that it distributes appropriate leaflets. This *Laboratory Manual* is directed toward the same end namely of providing concise and practical information for the guidance of clinicians in selecting taking handling and despatching material for laboratory examination. The Manual also contains information regarding the Public Health Law the Sanitary Code and the U.S. Postal Laws and Regulations in so far as these are relevant.

The Manual opens with a description of the organization of the Public Health Laboratory service in the State. The second part deals with admission of specimens, specimen outfits and their preparation biological products their distribution, use and reactions which may follow them, and the precautions to be taken. There then follows the main part of the Manual, occupying some 80 pages namely an alphabetical list of communicable diseases and the laboratory aid appropriate to them. This includes bacterial, protozoal, helminthic, virus and rickettsial diseases their nature the source of specimen to be taken and the best means of obtaining them followed in each case by an admirable description of the relevant therapeutic and prophylactic products provided by the laboratory with their dosages and means of administration. Further parts deal with examination relating to water sewage dairy product and with food utensils. There are brief chapters on recording and reporting results and of distribution of laboratory supplies.

The book is essentially for local use and will prove of most direct use to those having contact with the Division itself but it is full of useful practical information from which any clinician requiring laboratory services should profit and which fill a need existing in medical circles everywhere. Within little more than 120 pages it provides the practitioner with all the essential information which he may need regarding his contact with a routine laboratory and its service to him.

In the closing paragraph of the Introduction it is pointed out that cardinal principle of the Division has been that laboratory services should be consultative that close relations are necessary between the physician and the pathologist. This course should go far in promoting better relations in general and practical practice.

H. J. O'D. Lusk-Jaffer

VORER HANS. Grundriss der Tropenkrankheiten. 2. Aufl. of Tropical Medicine 143 pp 1947 Stuttgart Georg Thieme Verlag.

Restrictions which have been in force as the result of the recent war have rendered it desirable to produce a practical handbook in small compass for

the use of students attending courses at the well-known School of Tropical Medicine in Hamburg. The need for such a work has become more urgent because of the impossibility of acquiring standard books under the present conditions and the unsuitability of the larger monographs for the average student. The condensed nature of the handbook necessarily renders it unsuited for a detailed review. A list of the contents, however, gives some idea of its comprehensive nature and its adequacy for the objects it has in view.

The subjects considered are arthropods as disease transmitters, protozoal, spirochaetal, bacterial, virus diseases, rickettsias, helminthic diseases, fungus diseases, nutritional diseases, snakes, other poisonous creatures and laboratory methods. Illustrations are lacking.

Considering the synoptical character of this booklet the amount of practical information it contains is very considerable. *P. Manson-Bahr*

WLYER, Fritz. Grundriss der medizinischen Entomologie. Mit Einschluss der uebrigen medizinisch wichtigen Gliederflüssler. [Essentials of Medical Entomology.] 2nd Edition pp viii+132, 63 figs. 1948. Leipzig. Johann Ambrosius Barth.

The present book is a short introduction covering the whole range of medical entomology. It is written for the man with only a slight training in entomology and would be suitable for medical men taking some such course as that for a Diploma in Tropical Medicine. About half the book is general and half deals with the insects in a systematic arrangement.

The book opens with an account of the general classification and anatomy of Arthropods. The author then passes on to give an account of the outstanding points in the physiology and life history of insects. He refers to such subjects as growth, moulting and metamorphosis, the effect of temperature on the length of the life cycle, hibernation, which is closely dependent upon climate, and particularly temperature, and the climatic limits within which biological processes are normally conducted. Later in the book, the ticks are dealt with in a similar manner. The general account of parasitism gives a formal statement of the meaning of predator, parasite, etc., and points out that parasitism may be permanent or temporary, highly specific or not; it may occur at various stages in the life history. There are certain cases in which parasites are fatal to their prey. The author deals in a general way with venomous arthropods.

About half the book, some sixty pages, takes the Orders, Families, etc., of Arthropods which are of medical or veterinary importance and gives their morphological characters, the essential points in life history and in more detail an account of the blood sucking forms. There is some tendency to give a disproportionate amount of space to insects which are of very minor importance. For instance, the dragon flies which are only of interest because one or two of them are intermediate hosts of a flat worm parasitic in poultry, receive half a page. A similar space is given to the Rhagionidae, a family of flies of which a few species are blood suckers, one or two of which occasionally bite man in America and Australia. On the other hand the Anoplura or sucking lice of man and cattle receive only one and a half pages.

The author has certainly provided a brief account which covers the whole range of the subject. There is no equivalent recent book in English or French. His approach to the subject is zoological and for the most part anatomical and his presentation is solid, orderly and formal. The reader may well ask whether something could not be done to make these dry bones live. *P. I. Buxton*

ZELIFF C. CONNOR (M.S. Ph.D., Assistant Professor of Human Parasitology and Zoology, the Pennsylvania State College). *Manual of Medical Parasitology with Techniques for Laboratory Diagnosis and Notes on related Animal Parasites*. pp. xh + 159 68 figs. on 17 pls. & 44 coloured f.m. on pl. 1947. Pennsylvania State College [22s. 6d.]

This is a useful publication which hardly merits the title of a book. It consists mainly of a series of cyclostyled notes designed for the use of students taking a laboratory course in tropical medicine. Another useful purpose it can fulfil is to serve as a reference work for technicians or as a volume-meron for laboratory workers in the tropics. Commencing with amoebae these notes range through the familiar ground of flagellates, leishmaniae, trypanosomes, malaria parasites, coccidia and the whole range of helminthology. Medical arachnology and medical entomology are fully treated and in many instances keys to larval and adult characters are given. The last 40 pages are devoted to details of laboratory diagnosis and laboratory techniques. This section includes methods of faeces examination, preservation of specimens, concentration methods, mounting of entomological specimens, etc.

It is a matter for regret that the photographic reproductions of parasites and cells are so blurred and indistinct as in some cases to be almost undecipherable. This also applies to the legends, which are so much reduced as to be quite illegible. Reference is made especially to Plate VI where the reduction has been carried so far as to render the microfilariae unrecognizable even with a hand lens. The line drawings mainly devoted to entomology are quite distinct.

Appended there is a list of references, a glossary of generic and specific names of important human parasites and an adequate index. P. VANCEW-BLISH

REICHENOW, EDUARD. *Grundriss der Protozoologie für Ärzte und Tierärzte*. [Fundamentals of Protozoology for Medical and Veterinary Workers.] 2nd Edition. pp. vi + 99 77 figs. 1948. Leipzig Verlag von Johann Ambrosius Barth.

This is a second edition, somewhat enlarged, of the book which first appeared in 1943. The present edition appears to have been published under licence of the Soviet Military Authorities.

The conciseness and also compactness of the book give the impression that it was an *ad hoc* publication for the use of medical and veterinary officers during the 1939-45 war and, such, it would undoubtedly have been of great use.

The subject matter is probably arranged on the lines of the teaching at the Hamburg School of Tropical Medicine.

The first part of the book treats of the protozoa on general lines and calls for no special comment. The classification of the protozoa is given in a table and there is a smaller table enumerating the species parasitic in man.

The second part treats of the various divisions of the parasitic protozoa on conventional lines. The account is very complete within the severe limitations of space and the descriptions are clear and accurate as one would expect from so well-known an author.

The diagram of the life-cycle of the malaria parasite on page 64 shows a hypothetical exo-erythrocytic stage in the endothelial cells of blood capillaries, a guess now known to be incorrect.

Parasodium falciparum is given as a synonym of *P. intercalare*. This even if correct, only makes for confusion now that the former name is so universally used.

The book, as a whole, falls into the class of handbook, albeit a good one and can be recommended to anyone wishing a concise description of parasitic protozoa in German. H. F. SKIRRI

SUMMARY OF RECENT ABSTRACTS*

III MALARIA

Epidemiology

SHUTE (p 21) has contributed a note on indigenous malaria in Great Britain. DOELEMEN and VAN THIEL (p 670) refer to the epidemic of malaria at Middelburg, Holland, during the war, which was due largely to the fact that military horses kept in the town attracted the anophelines, which became infected on the gametocyte carriers normally present. In Germany malaria is now a serious problem in certain provinces, it has been introduced by returning soldiers and refugees and the lowered standards of health and nutrition have adversely affected the position. WEYER (p 1050) describes the situation, mentioning the vectors, which are races of *A. maculipennis*.

Writing of malaria in Czechoslovakia after the war, SNUPAREK (p 480) shows that the introduction of Rumanian and other troops from heavily infected areas spread the disease widely, and that wartime destruction created breeding places for the anophelines already present. *A. claviger*, *A. maculipennis maculipennis* and *A. m. messeae*. Epidemics of malaria have occurred since 1935 in the valleys of certain tributaries of the Danube in Rumania, and ZOTTA, *et al* (p 133) show that *P. vivax*, *P. falciparum* and (rarely) *P. malariae* were concerned. Man-made breeding places in river dams have encouraged the vectors, *A. maculipennis messeae*, *atroparvus* and (possibly) *maculipennis*.

The war had a disastrous effect on the malaria position in Italy, and CANAPERIA (p 229) shows that this was the result of destruction of bridges, dykes and drainage works, dispersal of staff, scarcity of drugs, over-population and the presence of non-immune troops. The increase in malaria occurred in the areas where the important vectors, *A. maculipennis labranchiae* and *A. sacharovi*, are found. Moreover, FERRARO (p 229) points out that as a result of war destruction, *A. sacharovi* has appeared in places in Italy where it was not previously found. Round Cassino, Italy, malaria spread widely as a result of wartime destruction, and GARACI (p 671) points out that up to 40 per cent of the infections were with *P. falciparum*, which was most common in autumn.

DE NEGRI (p 747) points out that the discovery of marsh gas at considerable depth, near Venice, has led to its exploitation for industry. One effect has been that from the bore holes there also emerges a large amount of saline water which has raised the salt content of neighbouring collections of water so that

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1948 v 45. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

they now encourage the breeding of *A. sackarovi* the most formidable vector in this area. MONACI (p. 747) also refers to the outbreaks of malaria which occurred in the neighbourhood of Venice from 1941 onward and reports that *A. sackarovi* was found where the endemic malaria was most severe. Increasing malaria to the north of Venice. PATRISI (p. 673) makes the point that *A. sackarovi* larvae have been found in canal water with a salt content as high as 72 per cent. The incidence of malaria was lowest where this mosquito was least abundant. BEADLE (p. 492) however found *A. sackarovi* breeding in water with very low saline content on the Venetian coast of Italy.

HÖRST (p. 28) describes an outbreak of malaria in German troops near Larissa in Greece most of the cases were due to *P. vivax*.

Late spring rains led to a severe outbreak of malaria in the Department of Algiers in 1948. *A. maculipennis* was abundant.

MATHEU (p. 22) gives a short account of malaria in part of Dahomey where spleen rates in children ranged up to 23 per cent. *P. falciparum* (the common parasite) SAUTET *et al.* (p. 856) draw attention to the frequency of *P. falciparum* in Mauritania.

DE AZEVEDO *et al.* (p. 968) report on a malaria survey of Portuguese Guinea, for details of which the original should be consulted.

SCHWETZ *et al.* (p. 230) as a result of an investigation undertaken along the eastern frontier of the Belgian Congo conclude that malaria does not spread there at altitudes over 1,700-1,800 metres and that the high plateaux are free. The chief vectors were not found at that height and though certain other anophelines were seen, they were evidently not important in transmission. SCHWETZ (p. 484) found high parasite rates round Lake Tumba in the Belgian Congo though the two mosquitoes *A. monoch* and *A. gambiae* were rare. SCHWETZ *et al.* (p. 748) note that *P. malariae* is very prevalent in both the Lubilash-Sankuru region and in the Katanga Province of the Belgian Congo although *P. vivax* is rare. They report on the anophelines found in these places.

HIRSCH (p. 671) records a survey of the people of Ta'eta Kenra where representatives of many tribes live. A high spleen rate and a low parasite rate in one place suggested that the common infection with *Schistosoma muriei* might be a cause of some of the cases of enlargement of the spleen. *P. falciparum* was the common parasite and *P. malariae* was also found, but not *P. vivax*. The vectors are *A. gambiae* and *A. foveolatus*.

At Kilimane in Portuguese East Africa the spleen rate varies from 58 to 77 per cent in children. *P. falciparum* (the common parasite) and *A. f. citri* and *A. gambiae* are the common vector. (RIBEIRO p. 231)

A malaria survey of Mauritius is reported by VERR and TAYLOR (p. 134). Malaria is largely confined to the coastal area. The average spleen rate in children living below 800 feet was 46 per cent and the rates were much less at higher altitudes. In one district the rate was 80 or more. Parasite rates are similar. The intensity of malaria is greatest in those parts where stunted malnutrition are most common and where infant mortality is highest. The vectors are *A. gambiae* and *A. f. citri* which are not very active in the old weather.

The New Hebrides have an evil reputation for malaria and MERRITT (p. 38) shows that it is the commonest disease and that it seriously affected United States troops during the war. *P. falciparum* is the common parasite, though *P. malariae* and *P. vivax* are also found. *A. punctulatus foveolatus* the abundant vector, it breeds in many kinds of water. Malaria not found further south (the Pacific than the New Hebrides). HURST *et al.* (p. 22) found spleen rates up to 84 per cent in children in part of New Guinea.

The incidence of malaria in the United States continues to fall though there are still hyperendemic areas in the south. FLETCHER (p. 231) *P. malariae*

infections are quite common in children (especially coloured children) in South Carolina (McDANIEL and HEMPHILL, p 856)

A malaria survey of Haiti is reported by PAUL and BELLERIVE (p 23), who found spleen rates of 29 in the lowlands, falling to 6 in the mountains. The highest rates were in children below the age of 4. The parasite rates were much higher, most of the infections being due to *P. falciparum*. *Anopheles albimanus* is ubiquitous, and *A. grabhami* is also common.

An epidemic of malaria in Venezuela (largely *P. vivax* in one town and *P. falciparum* in the country) is described by NIETO CAICEDO (p 24). The area concerned was the basin of Lake Maracaibo, and *A. albimanus* in the desert-like regions and *A. darlingi* in the jungle country were concerned in spread.

BATISTA (p 1051) has written a volume on malaria in Manaus, the capital of Amazonia, Brazil, where it is the chief endemic disease.

PIÑERO GARCIA (p 232) reports on malaria in Santa Fé, Argentina, where the common parasite is *P. vivax*.

Transmission

A discussion of species of *Anopheles* described in recent years is contributed by SENEVET (p 1051).

RAO (p 233) has shown that wingless mosquitoes have a strong tendency to walk towards dark places.

PEUS (p 26) in 1942 produced a German monograph on the anophelines of the Mediterranean region.

NOYAN (p 855) shows that in Turkey the common anophelines are *A. maculipennis*, *A. sacharovi* and *A. superpictus*, with *A. claviger* and *A. sergenti* in the south. He discusses the epidemiology of malaria in the various parts of the country.

KALANDADZE and KAVILADZE (p 296) report that in the western part of Iran Azerbaijan *A. maculipennis maculipennis* and *A. superpictus* are the most common vectors of malaria, *A. sacharovi* has a restricted distribution.

BUONOMINI and MARIANI (p 673) discuss the nomenclature of the *maculipennis* group. They distinguish 3 species—*A. maculipennis* (including race *messeae*, egg varieties *melanoon*, *fallax* and *subalpinus*, and biotype *cambournaci*), *A. labranchiae* (including race *atroparvus* and egg varieties *pergusae* and *sicaulli*), and *A. sacharovi*. They have erected a new group, *Maculipennia*, within the subgenus *Anopheles*, for these three species. UNGUREANU and SHUTE (p 136) have constructed a key for identification of the different varieties of *A. maculipennis* on the basis of wing scales. They consider that this group consists of at least four species rather than of varieties.

KETTLE and SELICK (p 571) show that the eggs of *A. maculipennis maculipennis* develop in 10 days at 10.6°C and in 4 days at 16.5°C, the eggs of *A. m. labranchiae* and *A. m. melanoon* take rather longer at these temperatures. VUILLET and LEVASSEUR (p 857) have exposed eggs of *A. maculipennis* to supersonic rays, and have noticed that the rate of development was accelerated. They discuss the phenomenon.

KETTLE (p 967) has studied the growth of the larva of *A. sergenti*, especially as regards the anal papillae in water of different degrees of salinity.

DE MEILLON (p 295) has published a comprehensive monograph on the anophelines of the Ethiopian Geographical Region, a most valuable work. MATTINGLY (p 137) has written on the early stages of certain Ethiopian anophelines, but his paper should be read in the original. SCHWETZ (p 296) has published a study of the mosquitoes (including anophelines) of the eastern part of the Belgian Congo.

In the Jebel Auiya reservoir, on the White Nile in the Sudan, LEWIS (p 968) found that *A. gambiae* is probably the main vector, but its breeding places are

well defined and can be treated with DDT in oil, or Paris green. *A. rufigris* is also probably a vector but breeds so widely that it is difficult to control. *A. pharoscensis* is very prevalent but not important and *A. / anisotarsis* found in the south where intensive house-spraying seems to be the feasible method of control.

Muirhead TROMSON (p. 482) has studied *A. gambiae* and *A. melas* in and around Lagos, and has tabulated the seasonal incidence. *A. melas* is found only within a mile of the shore and its abundance is determined mainly by tidal movements in the mangrove swamps. The abundance of *A. gambiae* on the other hand, is related to rainfall, since its breeding places are open shallow collections of water of many kinds. The sporozoite rate of *A. gambiae* is consistently higher than that of *A. melas* the former is relatively low when the mosquito is most plentiful, but may rise to 29 per cent. when breeding is least prolific. *A. gambiae* makes much use of houses for resting whereas *A. melas* rests more commonly outside these habits have an important bearing on the usefulness of residual insecticides. Both mosquitoes feed mainly after midnight, the period of greatest activity being between 4 a.m. and dawn. The breeding areas of *A. melas* are difficult to locate and the whole area covered with *Paspalum* is suspect but tidal swamp reclamation should eliminate all breeding.

WASSON *et al.* (p. 392) give an account of the bionomics of *A. mosquito* which breeds round the islands in the River Congo. It is a vector of malaria, and tends to rest on entering a house and then to feed and leave the house to digest the meal and mature the eggs outside.

FAIN and HEYWARD (p. 967) have recorded *A. mosquito* as the predominant anopheline of certain rivers in the Belgian Congo. *A. gambiae*, *A. / anisotarsis* and *A. / anisotarsis* were also found.

GILFARO (p. 137) has found *A. rufigris* naturally infected at Kano, Nigeria.

On the basis of precipitin tests Senior WHITE (p. 155) find that the anthropophilic index of certain Indian anophelines varies very greatly in different places, and according to whether they are caught in houses or cattle sheds. This may indicate the existence of biological races of these mosquitoes. RAO (p. 137) discusses the question of gonotrophic discordance in certain Indian anophelines: this refers to a state in which development of the ovaries does not keep pace with nutrition but is dependent on repeated feeding. It seems probable that mosquitoes in this state in which sexual activity is delayed are most likely to transmit malaria because they feed more frequently than more normal mosquitoes.

Senior WHITE (p. 571) has analysed a series of night catches of anophelines in Central India, where *A. / anisotarsis* is the known vector. *A. / anisotarsis* is found and is also probably a vector both when entered houses chiefly before midnight and before dawn.

GAYLER (p. 752) has made a survey of part of the Bengal Nagpur railway several species of anophelines were taken, including *A. / anisotarsis* infected specimens of which were found in the malaria season.

On the north coast of Madras the chief vectors are *A. / anisotarsis* and *A. / anisotarsis*. Salinity as low as 100 parts per 100,000 is the optimum for oviposition by *A. / anisotarsis* but half the larval production occurs in waters having 700-1,000 parts per 100,000. These and other findings by Senior WHITE *et al.* (p. 233) suggest two races of *A. / anisotarsis*.

The habit of the anophelines of Malaya were studied by NIX (p. 677) for details the original should be consulted. RIPP (p. 1057) has found two forms of *A. / anisotarsis* in Malaya one of which (dark wing) is found in the coastal plain and is a formidable vector the light wing form less important.

Epidemics of malaria occurred in Sarawak in 1944, which were due largely to intensive breeding of *A. / anisotarsis* partly because low rainfall enabled

brackish water to penetrate far up the rivers, and partly because spring tides flooded an area ravaged by war STRAHAN (p 749) states that although *A leucosphyrus* and *A umbrosus* may transmit along the coast, *A sundanicus* is responsible for the epidemic manifestations because it is so common

In a study of the anophelines used for transmission of malaria in connexion with the investigation of mepacrine in Australia during the war, MACKERRAS and ROBERTS (p 572) found *A punctulatus punctulatus* the most suitable It colonized readily and fed avidly on man, moreover, it is relatively long-lived, which, the authors think, is most important They detail the conditions which favour the mosquito, among which they mention freedom from disturbance WOODHILL (p 297) gives his reasons for thinking that there are two subspecies of *A punctulatus*, namely *A p punctulatus* and *A p farauti*, and that where these subspecies exist together there are hybrids between them *A kolensis*, which appears to be constant in its characters in the Solomon Islands, is not so in New Guinea, since it gives rise to both *punctulatus* and *farauti*, it also is probably a subspecies of *punctulatus* ROBERTS and O'SULLIVAN (p 968) have studied *A punctulatus punctulatus* and *A p farauti* in New Guinea, and show that the former is more anthropophilic than the latter After feeding, the females rest for a short time, and the application of DDT to the walls of houses is therefore a promising method of malaria control *A amictus lilli* in N Queensland shows habits similar to those of the *punctulatus* group

Quartan malaria is rare in the United States, and WELER *et al* (p 27) report a case in which infection was probably transmitted from a patient being treated with *P malariae*, by mosquitoes breeding near the hospital, to another man in the same hospital The need for screened wards under such circumstances is emphasized

YOUNG and BURGESS (p 1053) show that of 5 species of North American anophelines, *A maculipennis freeborni* was the most, and *A albanus* the least susceptible to strains of *P vivax* from certain other parts of the world In an examination of the infectivity of local strains of malaria parasites to *A quadrimaculatus*, YOUNG *et al* (p 674) in S Carolina found that even when the gametocyte density in the blood was extremely low the mosquitoes could become infected Patients without symptoms were as efficient as those with symptoms in infecting mosquitoes EYLES *et al* (p 1052) have allowed *A quadrimaculatus* to bite patients who have had *P vivax* malaria, at three periods—just before relapse, between attacks and at the end of attacks In each case some mosquitoes became infected Persons who have had this infection may be dangerous to the community in that they can infect mosquitoes even in the absence of clinical symptoms From their own investigations with *A quadrimaculatus* WEATHERSBEE and FROHNE (p 752) do not agree with the generally expressed opinion that the density of the vector is a major factor in the transmission of malaria They have found infected specimens when the density is exceedingly low They have also found gland-positive females in mule-stables, and they think that, for residual DDT to be effective, it should be applied to outside harbourages as well as to human dwellings

WILLIS (p 674) has investigated the olfactory responses of female *A quadrimaculatus*, if they have not had a blood meal they are attracted by the smell of the human arm, at 34°C and 70–85 per cent relative humidity VOGT (p 234) shows that the salinity tolerance of *A quadrimaculatus* larvae may be as high as 2,900 parts per million

Dispersal and feeding habits of *A freeborni* were studied by ROSENSTIEL (p 675) in California, who found that dispersal did not occur until July and was most active during September and October, up to 10 miles from the breeding places

The technique of rearing laboratory colonies of anophelines of the western United States is dealt with by HARDMAN (p. 298) for detail the original should be consulted. Similar papers have been contributed by BARRIS (p. 298) and GIGLIOLI (p. 299) these two authors discuss the rearing of *A. darlingi*.

FERNÁNDEZ MELÉNDEZ (p. 138) thinks that *A. scutellaris* may be an important vector in Cuba. It shows marked preference for human blood.

STACE and GILLITT (p. 577) note that in Trinidad *A. aquasalis* may travel 5 miles from its salt marsh breeding places. They discuss the breeding of *A. bellator* in the bromeliads of shade trees, and they have found that spraying these with 0.5 per cent copper sulphate kills the bromeliads. Plans have been made to use shade trees which are not parasitized by bromeliads.

GIGLIOLI (p. 483) has studied the house-frequenting habits of the mosquitoes of the British Guiana coast and shows that *A. darlingi* is the most common anopheline caught in dwellings. The domestic habits of this mosquito render the prospects of control by DDT residual house-spray excellent. FLOCH (p. 749) reports on malaria in French Guiana where *P. falciparum* is now more common than *P. vivax* (which was not the case in 1917) the common anopheline is *A. darlingi* but *A. aquasalis* and many other species are also found.

In Brazil as a whole PINOTTI (p. 237) states that 8 species of *Anopheles* have been found naturally infected. *A. darlingi* is the most important vector but *A. albipennis*, *A. tarsimaculatus* [*A. aquasalis*] and three species of *Heriodes* (breeding in bromeliads) are also important. The subgenus *Heriodes* in Brazil is discussed by PINOTTI *et al.* (p. 1053). CORTINHO (p. 969) describes the anophelines of Brazil, 6 species of which are vector — *A. darlingi*, *tarsimaculatus*, *cruxi*, *bellator*, *homunculus* and *albipennis*. In the Amazon region of Brazil, the chief vectors are *A. darlingi* and (in coastal areas) *A. aquasalis*. DEANE (p. 232) found that most infections were due to *P. vivax*.

PENIDO (p. 301) describes the malaria position in the region of the Rio Doce Brazil, where *A. darlingi*, *A. albipennis* and *A. aquasalis* are the chief vectors. The extent of the annual epidemics is determined by the extent of flooding from the river which overflows each year. At these times larval control is almost impossible but it is attempted during the dry season. Chief reliance is placed on Paris green and drainage but DDT will undoubtedly be used in future. *Anopheles darlingi* and *A. albipennis* are the chief vectors in the valley of the Rio Doce and *P. falciparum* was found by AMARAL and PENIDO (p. 77) in half of the positive blood slides seen in the area. In a description of the malaria history of part of Brazil SILVA (p. 673) shows that although several anophelines are indigenous only *A. albipennis* was taken in houses and found to be infected.

DE LUCENA (p. 676) has found *A. tarsimaculatus* breeding in water with a relatively high salt content (up to 33 gm. per litre) over 200 kilometres from the sea in Brazil. It is closely associated with outbreaks of malaria. *A. tarsimaculatus* is a name which has in the past included several species and varieties.]

CASTILLO (p. 740) mentions three malaria regions of Ecuador — the west coast, vector *A. albimanus* breeding seasonally, the inter Andes region, vector *A. pseudopunctipennis rivasdenisi* as the upper Amazon with its marshy vectors *A. (Heriodes) boliviensis* breeding in bromeliad and *A. darlingi* in marshes.

REY (p. 1053) gives an account of the known vectors of malaria in Cochabamba. Malaria shows seasonal prevalence in the Cafete Valley of Peru where the chief vector is *A. pseudopunctipennis* (ESTEL CASTILLO p. 570). The subgenus *A. pseudopunctipennis* is not yet defined. VILLALBA and VALDERAMA DEL PO (p. 300) have studied the habit of *A. pseudopunctipennis* in Peru.

Aetiology

A most important advance has been made in the understanding of the development of mammalian malaria parasites in the stage between injection of sporozoites and appearance of blood forms, by the work of SHORTT, GARNHAM and MALAMOS (p 388). These authors allowed large numbers of mosquitoes infected with *P cynomolgi* to feed on a monkey, and in addition they then ground up the mosquitoes in heparinized plasma and injected the suspension into the peritoneal cavity and into the muscles. Seven days later the pre-erythrocytic forms of the parasite were found within the parenchymatous cells of the liver. SHORTT, GARNHAM, COVELL and SHUTE (p 482) adopted a similar technique when they infected a human volunteer with very heavy doses of sporozoites of *P vivax*, both by the bites of large numbers of infective mosquitoes, and by the intravenous injection of an emulsion of infected salivary glands. The volunteer had, a long time before, been infected with *P vivax* but after this heavy inoculation liver biopsy revealed the pre-erythrocytic forms of *P vivax*, which were recognized in man for the first time. The details of the experiments which led to these important discoveries, and descriptions of the various stages of the parasites, are given in a later and more comprehensive paper by SHORTT and GARNHAM (p 762). The same authors (p 872) have shown that the exo erythrocytic schizonts of *P cynomolgi* may persist for 3½ months after sporozoite infection, and it is probable that this fact has a direct bearing on the occurrence of relapses.

HAWKING (p 388) reviewed some of his own material in the light of the findings of Shortt, Garnham and Malamos and confirmed their discovery. A more complete account of this work, with a description of the parasites is given by HAWKING *et al* (p 685).

YOELI (p 966) claims to have found non-pigmented malaria parasites (resembling *P vivax*) in bone marrow smears, together with leishmania.

BOYD and KITCHEN (p 393) have been able to show that in three strains of *P vivax* from the Pacific there were substantial immunological differences between one and the other two.

CIUCA *et al* (p 481) observed abnormal forms of sporozoites of *P vivax* and *P falciparum* in 17 and 32 per cent respectively, of *A maculipennis atroparvus* infected on gametocyte carriers in Rumania.

CHWATT (p 677) working in Lagos, shows that *P falciparum* invades mature and immature red cells indiscriminately and that *P malariae* is practically confined to mature cells. The degree of reticulocytosis varies according to parasite density. Persistent sub-clinical infections in African children are accompanied by increased erythropoiesis.

SHUTE and MARYON (p 751) have made a close study of a strain of *P falciparum* in a patient from the Belgian Congo. Details of its peculiarities should be sought in the original, but one notable point is that attempts to infect *A maculipennis atroparvus* in England failed.

SAUTET (p 670) thinks that spontaneous regression of malaria in any region may be the result of a limited capacity of the strain of parasite to produce gametocytes, and illustrates his views by reference to findings in Corsica and Russia.

MACDOUGALL (p 26) has detected chromosomes in the male gametes of *P vivax* and *P falciparum*.

MOSNA (p 136) describes a method for producing flagellation of microgametocytes *in vitro*.

SAUNDERS and SCOTT (p 135) have preserved *P vivax* in a viable condition for as long as 37 days by freezing infected citrated blood at -75°C and storing at -50°C .

BLACK (p. 25) has used a method of staining (which he describes) in his studies of the consumption of haemoglobin by malaria parasites.

Pathology

MACGRAITH *et al* (p. 234) refer to necrosis of the inner two-third of the hepatic lobules which they have observed in fatal malaria, and suggest that this is a result of anoxia due to reflex constriction of part of the hepatic venous system. CALEY (p. 301) discusses these findings and quotes his clinical experience in Siam, which suggested that there were hepatotoxic and encephalotaxic strains of *P. falciparum*.

Experimental work with carbon tetrachloride and other substances, undertaken to help in elucidating the pathogenesis of the centrilobular liver changes found in malaria, led ANDREWS and MACGRAITH (p. 678) to think that the necrosis is due to anoxia, possibly resulting from toxic swelling of the parenchymatous cells which constrict the blood channels. In an exposition of the pathological processes in malaria MACGRAITH (p. 1054) explains his conception of the part played by anoxia and circulatory disturbances. The latter may be due to reflex vascular mechanisms or to mechanical obstruction from swelling of endothelium or accumulation of cells, perhaps with local loss of fluid—the result is local tissue anoxia. The effects of these processes vary according to the vascular and tissue structure of the organ concerned and in the brain may lead to necrosis. The circulatory changes during a malaria paroxysm are probably of central origin, the vasomotor centres being probably stimulated by substances originating during parasitic sporulation. ANDREWS (p. 1054) shows that the liver changes in malaria (centrilobular degeneration) when they occur are the result of tissue anoxia and may be the result of reflex constriction of the smaller radicles of the hepatic vein. He discusses the mechanism of this constriction and the morbid histology of the liver.

LYNCH (p. 300) discusses the blood and bone marrow in the various stages of malaria.

Tests

NELSON (p. 30) found false positive serological test for syphilis in 3 per cent of 200 Europeans suffering from *P. falciparum* malaria in West Africa. These became negative shortly after treatment. CHAM (p. 31) also finds that false positive results are rare in malaria (less than 1 per cent in African, in the Congo) except perhaps in Europeans undergoing the first attack. MASON (p. 1046) has never found the Hecht reaction positive in malaria without syphilis, provided that the test has been properly carried out.

ZIFF (p. 1057) shows that the Tremar photometric modification of the Henry reaction is not suitable for rapid diagnosis of malaria, though it may have a value in diagnosis and prognosis if a series of test are performed.

DULACRY *et al* (p. 857) show that the complement titre of the serum is usually diminished in induced malaria and that it reflects the severity of the disease.

KLEBERG and BERNBAUM (p. 496) have studied liver damage in malaria by tests relating to serum proteins.

MAKARI (p. 344) has devised an intradermal test with antigen prepared from chicken blood infected with *P. gallinaceum* which gives a positive reaction in a high proportion of people who have had malaria and (weakly) in only a small proportion of non-malarial control persons. The test may be useful in masked or latent malaria. The same author (p. 395) has remarked that the incidence of positive tuberculin test is higher in patients with chronic malaria than in controls.

BROOKE and DONALDSON (p 1056) have shown that if slides are stained in bulk, blood may, under certain conditions, be transferred from one slide to another

ARU (p 970) gives details of a method of concentrating malaria parasites in blood, by haemolysis and centrifugation, for the purpose of diagnosis BERLINER *et al* (p 964) describe a centrifugation method of concentrating *P vivax* in blood, details should be sought in the original abstract

Clinical Findings

In a long and comprehensive article, FAIRLEY (p 20) describes the course of events in malaria induced by the bite of infected mosquitoes, as it was elucidated during the experiments made on volunteers in Australia during the war This study of parasitaemia in the untreated volunteers and in those treated with mepacrine and other drugs depended chiefly on the evidence obtained by subinoculation of blood The account should be read in the original

MELLINKOFF and HIGGINS (p 396) show that in malaria the pulse rate may range from tachycardia (as in many bacterial infections) to bradycardia (as in typhoid fever)

SOYSA (p 395) describes the clinical features of various forms of malaria seen in the military hospitals of Ceylon

In the Belgian Congo DUBOIS (p 235) has found a much higher splenic index in women than in men, though there is no evidence that women suffer more than men from malaria It is probably a question of relaxation of visceral ligaments in the erect position, and the author thinks that the splenic index in adults may therefore be misleading

Discussing the effect of malaria on pregnancy, KULCSAR (p 489) agrees that treatment should not be delayed if there is clinical suspicion of malaria, mepacrine is well tolerated

HERNBERG (p 236) shows that *P vivax* malaria is more benign in Finland than in more southern countries, he gives an account of the clinical course of the disease He (p 302) has found 4 instances of renal disturbance in 1,500 patients with benign tertian malaria in Finland [in the original abstract it was wrongly stated that they were cases of malignant tertian malaria] In all cases the symptoms were relieved by antimalaria treatment The same author (p 143) has seen transitory myocardial affection in 9 of 596 patients with benign tertian malaria

BENHAMOU *et al* (p 302) report a case of haemorrhagic meningitis associated with *P vivax* infection, the condition cleared under treatment with quinine

Neuropsychiatric symptoms occurred in the course of malaria in the Mediterranean during the war, and in some cases *P vivax* was incriminated, though most were due to *P falciparum* BOSHES (p 396) reports a case of meningoencephalitis due to *P vivax*

BOYD (p 138) reviews his experience with therapeutic *P vivax* malaria, in relation to the development of immunity Tolerance to the presence of parasites in the blood is the first sign of immunity, but later a strong destructive mechanism is developed, which does not seem to act on sporozoites but destroys trophozoites The completely refractory state may last a long time and there is no evidence that it depends upon a persisting latent infection, the immunity is not humoral

COOPER *et al* (p 140) have been able to infect by intravenous injection of trophozoites, patients who had previously been infected by mosquitoes with the homologous strain of *P vivax* but whose attacks had been suppressed by drugs, and who were in a latent period

WHORTON *et al* (p 235) discuss the immunity provoked by the Chesson strain of *P vivax*, giving details of the parasite densities at various stages

The incubation period of the Chesson strain of *P. vivax* in relation to the number of trophozoites or sporozoites infected, is discussed by WILKINSON *et al.* (p. 139). Some of the same workers (p. 139) have shown that when the incubation period was short the relapse rate was high and the latent period before relapse was short. The types of fever induced by this strain are described (p. 140) they are not exceptional.

As a result of a study of infection induced in patients with neurosyphilis by means of several Mediterranean and Pacific strains of *P. vivax* LOTIC *et al.* (p. 236) have noted differences between strains in incubation periods and average parasitaemia. They quote their observations in detail, and note that Negroes in the United States were refractory to these strains.

Discussing induced malaria for the treatment of general paralysis in Holland, BYLAKER and WIERCKEL (p. 487) make the point that a Dutch strain of *P. vivax* tended to have a long incubation period (6-9 months) and could not therefore be used. The Horton (Madagascar) strain does not show this feature but there is nevertheless, reciprocal immunity between these two strains.

BIANCO *et al.* (p. 28) discuss relapses in *P. vivax* malaria, admitting that there are unknown factors which determine these relapses. All effort made by the authors to precipitate relapses failed. In treatment mepracrine is better than quinine but the best results were obtained with plasmoquine-quinine. PURMAN *et al.* (p. 488) discuss the periodic phenomena of induced *P. vivax* infections: there seems to be a 12-day rhythm in parasitaemia and in recrudescences for which the authors cannot account. Details should be sought in the original. A study of relapses in American servicemen returned from the Pacific and the Mediterranean was undertaken by EYLES and LOTIC (p. 859) who show that in *P. vivax* infections parasites could usually be found some 3½ days before the febrile paroxysm of relapse and that the median threshold count was about 3,200 per cmm. Most relapses took place within 120 days (mean 81) of the preceding clinical attack, and most patients did not show parasites between attacks.

ROSS (p. 141) gives a long account of *P. falciparum* malaria as it is seen in Europeans in Kenya. On the whole he does not agree that its manifestations are very protean except in children. Treatment is very satisfactory with quinine or mepracrine and there is little tendency to relapse.

SCHNEIDER (p. 679) reports a case of haematemesis apparently due to *P. falciparum* malaria. BOXKE (p. 30) describes two cases of malaria in which there was severe haemorrhage from nose, stomach or bowel.

RATU (p. 838) describes a case of glycosuria in the course of malaria, caused, presumably, by an effect of the malaria infection on the islets of Langerhans. Treatment with paludrine cured the condition.

SPITLER (p. 840) reports a case of relapse of *P. malariae* infection 76 years after the original infection. BORD (p. 345) notes that in one patient a naturally induced *P. malariae* infection has lasted more than 11 years. ROGERS (p. 143) reports a case of transfusion malaria (quartan) arising from blood which had been stored for 3 days. The donor did not give a history of malaria but it was proved that his blood contained parasites. He had been a ship engineer in the East.

CHEN and WU (p. 143) report transfusion malaria in China, but not if the recipients were given quinine (1.2 gm. daily) for 5-7 days after receiving the blood.

MALARIA

ERIKSSON, T. Studien über die Malaria und *Anopheles* in Schweden und Finnland [Studies on Malaria and *Anopheles* in Sweden and Finland] *Acta Path et Microb Scandinavica* 1945 Suppl 59 88 pp., 31 figs [70 refs] [Summary taken from *Rev Applied Entom* Ser B 1948, Oct., v 36, Pt 10, 158]

In this detailed study of the history of malaria in Sweden and Finland, where it was widespread in the 19th century, the author discusses the factors that contributed to its appearance and spread in endemic and epidemic forms in those countries, and those that led to its virtual disappearance—the regression began soon after 1860 in Sweden, but not until well into the present century in Finland. The malaria centres in both countries at different periods are shown on maps, from which it appears that coastal towns were more seriously affected than rural districts. In Sweden, the disease occurred chiefly in the south-east, its distribution corresponded closely with that of its probable vector, *Anopheles maculipennis*, Mg., of which vars. *tyficus*, *nassiae* Flm., and *atroparvus*, van Thiel are present, but no correlation has been found between its transmission and any particular variety. In Finland the disease was limited mostly to the extreme south-western coastal areas although *A. maculipennis* also occurs much further to the north.

The spread of malaria in northern Europe in the 18th and 19th centuries is attributed mainly to the increase in trade and shipping. Since epidemics in Sweden and Finland often followed epidemics in central and southern Europe after intervals that increased with the distance northwards, it is concluded that the malaria was imported from these areas, and that the parasite concerned was probably *Plasmodium vivax*, which was the species responsible for isolated cases reported in Sweden in 1939.

The regression of malaria in Sweden and Finland is attributed mainly to the increased use of quinine and to a lesser extent to improved social and hygienic conditions, and not—as was suggested by Flensburg (1913), to the decline in summer temperatures that has been observed or to a decrease in the number of *Anophelinae*. The theory that the *Anopheline* vectors have changed to zoophilous habits is also rejected, since an epidemic occurred in Finland in 1920.

HENRIK, C. A. & TUOMITA, A. Incubation Time of Malaria Tertiana during an Epidemic in Finland in 1945. *Acta Med Scandinavica* 1948, v 130 Suppl 206 544 9 1 fig. 27 refs.

During the war malaria was of frequent occurrence in the Finnish army but in the home districts only sporadic cases occurred. In 1945 there were 1,252 cases of which only 85 were in the peace-time army. A more or less complete history was obtained in 868 cases. Of these 868 patients only 12 were women. There was no case below the age of 15 or above the age of 53—more than one-third of the patients were in the 20–25 age group. Summer temperatures in 1945 were unfavourable for malaria transmission anywhere north of Helsinki. But malaria cases were distributed widely throughout the country. By mid-April 112 cases had occurred; there are no mosquitoes in Finland at that time of the year. There were 440 cases in May and 352 in June; thereafter there was a constant decline in incidence. It is evident that the majority of the patients were not infected in 1945—infection by hibernating mosquitoes was a remnant of the previous year, as the districts in question had been free from malaria in the previous year.

Replies were received from 593 patients as to their whereabouts in the summer of 1944: nearly all of them had been on military service in the Carian theatre. Only 17 patients had been at home and only 5 on other fronts. Thus the majority of the patients had developed malaria after incubation period varying from 5 to 13 months.

The authors believe that increasing light determines increased virulence of the plasmodia. In this land of short summers autumn infections are especially likely to remain quiescent till the following spring.

— & CARTONNIER M. Groupes ethniques et répartition des hématozoaires en Indochine méridionale. [Ethnic Groups and Distribution of Plasmodia in Southern Indo-China.] *Ibid.*, 361-4 2 figs.

Populations from the healthier deltaic region of Tonking were transported to hyperendemic malarious region in the high plateaux of Southern Annam and in Cambodia. Conditions at the time precluded the use of prophylactic medication. Some years later the observations recorded in these papers were made. The very high degree of malaria infestation of the children of the Tonkingese immigrants did not differ significantly from that of the indigenous Moïs and Cambodian children, but there was a most remarkable difference in the prevalence of the species of *Plasmodium*. Among the indigenous children in Loth Annam and Cambodia *P. falciparum*, *P. vivax* and *P. malariae* were always found in that order of frequency, *P. falciparum* greatly preponderating. In the children of the immigrant population from Tonking *P. malariae* was always much more prevalent than *P. vivax* and in one instance more prevalent than *P. falciparum*. The indigenous and immigrant groups were living under exactly similar conditions and were exposed to attack by the same vectors. A *minimum* in most places, *P. pyrocephalus* in others. Further research is necessary to determine whether the relative resistance to *P. malariae* is a racial characteristic of the indigenous population acquired perhaps by prolonged exposure to infection by that species.

DILLBOYE P. Contribution à l'étude de l'état de permanence antipalustre des peuplades Moïs du Sud Indochinois. Antimalarial Prevalence among the Moïs of South Indo-China. *Bull. Soc. Path. Exot.* 1943, 3: 41 Nos. 5 B 419-26. 12 refs.]

The resistance to malaria displayed by aboriginal Moïs in the intensely malarious high plateaux of south Indo China has been described by FAYE and PROBY and others (this Bulletin 1943, 37-39). The present author has recently carried out an examination of 633 children and 129 adults of four groups of these people.

The parasite index of the children was three times as great as that of adults. Though the parasite index of adults was high in some groups the number of parasites found in positive films was comparatively very low. The plevic index of children was two to three times as high as that of adults. Very large spleens were common among the children whereas the plevic rarely exceeded more than one or two finger breadths below the costal margin in adults. Gametocyte carriers are much less frequent among the adult. *P. malariae* infections decrease in frequency with advancing age but *P. vivax* infections

are relatively more frequent among adults than among children. In this respect the Moïs differ from the malaria-resistant races of Central Africa and elsewhere. *P. falciparum* is the most prevalent infection of both child and adult, mixed infections are extremely rare among adult Moïs, common among children. The acquisition of a state of premunition is costly to the Moïs, the infant mortality rate from malaria is extremely high.

Norman White

DELBOVE, P. *Plasmodium malariae* et prémunition antipalustre en Indochine méridionale [*P. malariae* and Antimalarial Premunition in Southern Indo-China] *Bull Soc Path Exot* 1948, v 41, Nos 5/6, 356-8

Annamites who were transported to hyperendemic malarial regions of southern Indo-China without any measures of malaria prophylaxis suffered much from *P. malariae* infection. In certain places this was the predominant type of malaria infection among them. Among the highly infected children of the indigenous populations of these same areas, *P. malariae* infections are relatively rare and always much less prevalent than *P. falciparum* and *P. vivax*. It would seem that the local Moï infant has an inherited resistance to *P. malariae*. It is interesting to note that in a study of congenital malaria in south Indo-China, *P. malariae* was more commonly found in the umbilical cord than either of the two other species of *Plasmodium*. This resistance to *P. malariae* increases with age. The examination of 2,142 individuals in four of the most unhealthy areas of south Indo-China gave the following results —

	Number examined	Parasite index	<i>P. vivax</i>	<i>P. malariae</i>	<i>P. falciparum</i>
Children	933	76.8 per cent	23 per cent	10.2 per cent	43.6 per cent
Adults	1,209	26.6 per cent	10 per cent	2.4 per cent	14.2 per cent

At least two factors enter into this process of immunization, an innate resistance to *P. malariae* and a state of premunition resulting from multiple and repeated malaria infections. In conditions such as these one can ignore the hypothetical intervention of a vector species specially adapted to the transmission of *P. malariae*.

Norman White

DELBOVE, P. Recherches sur l'état de prémunition antipalustre des collectivités annamites importées en zone hyperendémique de Cochinchine [*Antimalaria Premunition of Annamites transported to Hyperendemic Malarial Regions of Cochinchina*] *Bull Soc Path Exot* 1948, v 41, Nos 5/6, 427-33

Lack of prophylactic drugs was responsible for a greatly increased prevalence of malaria on most of the rubber plantations of Cochinchina. The observations here recorded were made on a particularly unhealthy plantation where the regular administration of quinacrine and premaline had ceased in December 1942. The labour force concerned had come from Tonkin. They were examined on four occasions between July 1943 and October 1944. The workers were divided into 3 groups according to their length of residence on the plantation at the time of the first examination: more than 5 years, from 2 to 5 years, from 1 to 2 years. The endemic malaria was particularly severe. The spleen index was lower in the first group than in the other two but was above 50 per cent on three of the four examinations. The parasite indexes showed less difference but the gametocyte index was markedly lower among workers of

more than 5 years' residence who had developed a manifest if slight resistance to malaria. Very large spleens were still common among this resistant group. The prevalence of *P. vivax* and *P. malarie* in the blood of the three groups was about the same. *P. falciparum* infections were less intense in workers who had been more than 5 years on the plantation but it remained the predominant parasite in all groups. During the observations *P. malarie* infections were on the increase while *P. vivax* infections decreased. Mixed infections were frequent among the new arrivals but were not seen among the group having 5 years' service.

Premunition in this part of Indo-China is difficult to acquire. Acquired resistance is ephemeral and never reaches the indifference to infection shown by adult aboriginal Moïs. Only extremely rigorous control and social measures succeeded in averting a catastrophe on the plantation in question.

DE MEIRA, M. T. V., SIMÕES, T. S. & NOGUEIRA, J. F. P. Observações sobre sazonalidade nas Ilhas do Sal, Boa Vista e S. Nicolau (Cabo Verde) (Malaria in the Islands of Sal, Boa Vista and S. Nicolau, Cape Verde Islands.) *A. Inst. Med. Trop. Lisbon*, 1947 Dec. v. 4, 13-38 [15 refs.] English summary.

The authors give the results of a malaria survey carried out in three of the Cape Verde Islands during November 1946 to January 1947.

Sal is the most northerly of the eastern sub-group of islands. It covers an area of 216 square kilometres and has a population of about 1,000, two-thirds of whom are half-castes. Most of the island is flat. Its climate is equable; the mean annual temperature is 24.7°C., the mean annual rainfall 129 mm. About half the population lives in the capital Santa Maria. Agriculture is almost non-existent; the rainfall is deficient and the soil poor. Conditions of life are precarious; dwellings are most unsatisfactory from a sanitary point of view; scarcity of fruit and fresh vegetables engenders vitamin deficiency. Infant mortality is excessive about 22 per cent of the total mortality; the chief cause being enteritis. During recent years malaria cases have numbered from 31 to 75.

Of 159 children between 7 and 14 years of age 14 had a palpable spleen. Only one of these children harboured malaria parasites *P. malarie*. Nine adult *Anopheles gambiae* were captured in one house; the larvae of this species were found in several places in a locality some 6 km. from Santa Maria. It was here that the patient with the positive blood smear lived.

Boa Vista forms part of the eastern sub-group of the archipelago. It (220 square kilometres) supports a population of 3,000; it is the third largest island of the group. Like the other islands it is of volcanic origin and has 11 hills varying in height from 700 to 337 metres. Two winding streams with low banks and irregular beds allow water to stagnate in places for many months after the rains.

Malaria cases are reported each year; a severe outbreak in 1943 caused 368 cases with 11 deaths. The authors examined 349 children from 1 to 14 years of age; 50 had palpable spleens (14.3 per cent). One of the children was infected with *P. malarie*. Search for adult and larval anophelines resulted in the capture of a single adult female *A. gambiae* in a dwelling house.

S. Nicolau is the most eastern of the northern sub-group of islands. It (343 square kilometres) has a population of 10,000. It has three mountains over 1,000 metres in height. There is considerable emigration of the population

in years of scarcity consequent upon deficient rainfall, and returning emigrants are frequently heavily infected with malaria. The total deaths from all causes over a nine-year period were 5,996, of these 61 were ascribed to malaria. Years of heavy malaria incidence have generally been marked by heavy rainfall and the return of infected emigrants from the isles of Santiago, S. Tomé, and from Angola, etc. The spleen index of 1,015 children aged 2 to 12, who had never left the island, was only 4.4 per cent. Blood examination of these children revealed no malaria parasites. One child suffering from an indigenous *P. vivax* infection was found during the survey. No adult anophelines were captured. Numerous larvae were found, these were all *A. pretoriensis*. [See also this *Bulletin*, 1948, 45, 1122, 1129.]

HOCKING, K. S. & MACINNES, D. G. Notes on the Bionomics of *Anopheles gambiae* and *A. funestus* in East Africa. *Bull. Entom. Res.* 1948, Dec., v 39, Pt 3, 453-65, 5 figs. [10 refs.]

Short accounts are given of some investigations into the bionomics of *Anopheles gambiae* and *A. funestus* at Taveta in Kenya during November, 1944 to June, 1945.

Night collections of anophelines in huts and tents at intervals of three hours showed that out of nearly 5,000 female *A. gambiae*, more entered between 1 a.m. and 4 a.m. than at other times and that there was no entry peak at 6 a.m. as has been recorded at other places. Of about 400 female *A. funestus* the greater number entered the huts just before dawn and with this species there was evidence of an entry peak at about 6 a.m. Of 324 male anophelines, 320 were captured after 4 a.m.

Illustrations show the external abdominal appearance of anophelines in each of the five stages of ovarian development. Stage V females of both species were isolated at 25.5°C and a diagrammatic record was kept of the changes in their external appearance after oviposition and after feeding. It was found that the mean interval between egg layings for both species was 4½ days. In a hut occupied by two Africans, morning sprays and mosquito collections made at intervals of one, two and three days showed no significant difference between the sizes of the catches, and from this it is concluded that the mosquitoes did not spend more than twenty-four hours in the hut.

Anophelines were collected daily and later every fourth day from two huts. Females were grouped according to their external abdominal appearance, this indicated that they entered the huts in approximately equal numbers each night and that there were enough of each stage either outside or in other huts to maintain these numbers in the two experimental huts.

The daily collections were then continued in the two huts but as far as possible all mosquitoes in twenty-eight other huts were killed. The collections from the two huts then showed that the numbers of those in the later stages I and II were maintained, while the numbers of those in the later stages III, IV and V must have been resting in some of the other huts and not in the bush, and that those entering the experimental huts were either newly emerged or newly returned from egg laying.

To sum up, *A. gambiae* and *A. funestus* did not spend more than twenty-four hours in any one hut. They moved from hut to hut and females did not rest in the bush in the daytime unless they were just emerged or just before and just after laying eggs.

MACAN T T Mosquitoes and Malaria in the Kabaw and Kale Valleys, Burma. *Bull. Entom. Res.* 1948, Aug., v 39 Pt 2 237-68 2 text figs. (1 map) & 2 figs. on pl. [10 refs.]

The Kabaw and Kale Valleys, latitude 23° to 25° N., lie to the east of the high mountain range separating the plains of India and Burma. They are from 4 to 10 miles wide and are bounded on the east by a range of hills that separates them from the valley of the Chindwin. The total length of the two valleys is some 250 miles—the middle 100 miles of this distance along the road from Tamu to Hakmoeyu were alone surveyed. Population is very scarce in the Kabaw Valley and clearings are few and small. In the Kale Valley the population is denser—the whole of the centre of the valley has been cleared—rice is the main crop grown. The valleys are about 500 feet above sea level. One of the chief land routes from India to Burma runs through the two valleys. The valleys drain through a gorge in the eastern side of the valley.

June to September inclusive is the rainy season—rainfall is light at other seasons. Temperature is fairly high throughout the year. The inhabitants live in Burmese-pattern dwellings raised on poles some 6 or 7 feet above the ground.

Before the war there was very scanty knowledge regarding malaria and mosquitoes in this area. In 1942 part of the Allied forces retreated through these valleys—the spleen rates of many of these villages were then determined. In 1944 the author was in charge of a party from a Malaria Field Laboratory and remained in the valley on and off until May 1945. Spleen rates show that the malaria risk is uniformly high throughout the valleys—only one village out of 23 examined had a spleen rate under 60 per cent. Malaria transmission takes place throughout the year and is intense from May to December inclusive.

Seventeen species of *Anopheles* were recorded. During the rains the common species were *A. minimus*, *A. leucosphyrus*, *A. philippinensis*, *A. pyreticus*, *A. annularis*, *A. bitarsus* and *A. negus*. *A. minimus* is only locally abundant at this season and *A. leucosphyrus* is confined to the forest. When the rain ceases *A. leucosphyrus* and *A. negus* become rapidly reduced in numbers—the prevalence of *A. philippinensis*, *A. pyreticus*, *A. annularis*, *A. bitarsus* and *A. barbirostris* which breed in larger bodies of stagnant water such as rice fields decreases more slowly. *A. minimus* and *A. maculatus* are the only common and widely distributed species in the dry season.

During the dry season, *A. minimus* is the only vector. *A. maculatus* does not appear to bite man. In September the sporozoite rate of *A. minimus* was only 0.31 per cent. the important vector in the rains season among 4 species operating in the forest appeared to be *A. leucosphyrus*—how important it is as a vector in peace-time is difficult to assess. *A. minimus* at times find day time shelter in the forest when this comes close to the village—night arches in houses are important in the study of the mosquito population.

Larvae identified as *A. pulli* & with the aid of standard Indian key invariably proved to be *A. philippinensis* on emery, etc.

(A summary does small justice to the large amount of detailed information contained in this report.)

BERTI, A L & MONTESINOS, M Cultivos de arroz en relación con la malaria el problema en Venezuela [Rice-Growing in connexion with Malaria the Problem in Venezuela] *Cuad verde Com ejecut 3a Conf interamer Agric* Caracas 1946, No 52, 33 pp, 5 figs, 2 folding maps & 4 folding graphs [10 refs] [Summary taken from *Rev Applied Entom* Ser B 1948, Oct, v 36, Pt 10, 175-6]

The history of the relation between rice cultivation and malaria is reviewed, and the relative importance of the introduction of large numbers of workers and of the various cultural methods in causing outbreaks of malaria in the neighbourhood of rice fields is discussed. In Venezuela, where rice cultivation is of considerable importance, *Anopheles albimanus*, Wied, and *A pseudo-punctipennis*, Theo, breed freely in the flooded fields. The former is one of the two chief vectors of malaria in the country and the latter is stated to be a suspected vector.

Two serious outbreaks of the disease due to Anopheline breeding in newly established rice fields recently occurred in the state of Aragua, at La Victoria in 1943 and at Cagua in 1944. The rice-fields at La Victoria were about 1½ miles from the town, but those at Cagua practically adjoined it. In both cases, continuous flooding was used, and the vector was *A albimanus*. Maps of both districts and graphs indicating the course of the epidemics are given, and the numbers of Anophelines taken in traps with animal bait are shown in tables and graphs. At La Victoria, the fields were first flooded in May-June, malaria broke out in the town in June and was at its height in December. No breeding places of *A albimanus* were found in the area other than in the rice-fields, the various traps set up showed that the adults could fly for rather more than 1½ miles from the fields and that control measures against the larva greatly diminished their numbers, particularly in the more distant traps. These measures consisted in the application to the water surface at intervals of six days of 3 per cent Paris green in ash or road dust, which did not injure the rice. These and other anti-malaria measures were adopted in 1944, and the number of cases was much reduced.

The fields at Cagua were sown at different times and harvested throughout the year but again the outbreak began in June, suggesting that if the crop were harvested before that month, the danger might be avoided. Other breeding places were present, but only 1 per cent of the larvae taken were found outside the rice-fields. As no Paris green was available, a mixture of sawdust and kerosene was used against the larvae, but did not give good results.

As a consequence of the outbreaks, legislation was passed prohibiting the cultivation of rice by artificial irrigation near towns except under permit from the Division of Malarology. Permits have been issued subject to the proper levelling and preparation of the land, the use of intermittent drainage (four days flooding and four days draining) and the application of larvicides. Land that cannot be drained dry in four days may not be used for growing rice. The economic aspects of rice cultivation and the costs of epidemics and of control measures are discussed.

GÓMEZ MARCANO, A Infección oocística natural de los anofelinos de Venezuela Estado actual de las investigaciones [Natural Oocyst Infection of Venezuelan Anophelines] *Archivos Venezolanos de Patol Trop y Parasit Méd* 1948, Jan v 1 No 1, 86-92. English summary

DOUGET G. Note préliminaire sur l'emploi du S.N. 7618 en milieu malarial hyperendémique [Preliminary Note on the Use of S.N. 7618 (Chloroquine) in a Hyperendemic Malarial Locality] Ann. Soc. Belg. de Méd. Trop. 1947 Dec. 31 + 27 No. 4 341-6.

These observations concern 50 school children 6 to 7 years of age in Leopoldville. Twenty five were each given a single dose of 0.125 gm. of S.N. 7618 (chloroquine) once a week. The remaining 25 children were untreated controls. When the experiment started on the 15th of March, the end of the rainy season, the parasite index of the treated children was 84 per cent. and of the control group 80 per cent. Eighty per cent. of the infections were *P. falciparum* the remainder *P. malariae* there was no *P. vivax*.

Six days after the first dose of chloroquine the blood of the treated children was completely free from schizonts. Gametocyte carriers, however, had increased from 8 to 13. Six weeks after the commencement of treatment the blood of the treated children was completely free from parasites and remained so during the period of observation. The parasite index of the control children varied from 84 to 98 per cent. There was no absence from school on account of fever among the treated children whose general condition and intellectual activity were noticeably better than those of the control children. There was no sign of drug intolerance.

In addition a group of 30 adult Europeans each took 0.25 gm. of chloroquine once a week for six months. An examination of their blood was made once a month: no malaria parasites were found.

ATCUTLEY J. A., YOUNT E. H., HOSTED J. R., PULLMAN T. N., ALVING A. S. & EISENBERGER Lillian. Reactions observed during Treatment with Pentagaquine, administered with Quinacrine (Atabrine), Metachlorquine (SN 11 437), and with Sulfadiazine. J. National Malaria Soc. 1948 June + 7 No. 118-24 4 figs. 11 refs.

It has been shown that pentagaquine monophosphate has less curative effect against *P. f.* infections when administered alone than when given concurrently with quinine this Bulletin 1948 45 845. Tests were carried out with several other antimalarial drugs to determine whether they are capable of reinforcing the action of pentagaquine in like manner. None displayed activity comparable with that of quinine. During the course of the trial certain toxic reactions were encountered. These form the subject matter of this paper.

All subjects received 60 mcm. of pentagaquine base (50 mcm. monophosphate) a day in six equal divided doses, for 14 days. In addition 5 patients with malaria each received 16.8 gm. of paludrine citrate in 14 days. The action of pentagaquine was not thereby increased. In 1 patient with malaria who received 5.63 gm. of chloroquine diphosphate in 14 days the toxicity of pentagaquine was not thereby increased.

Quinacrine was given concurrently with pentagaquine to 5 patients with malaria. The 4 patients who completed the treatment each received 5 gm. of quinacrine dihydrochloride in 14 days. A mild hemolytic anaemia occurred in the 5th patient. Haemoglobin fell from 15 gm. per 100 cc. to 8.3 gm. on 11

when given concurrently
fell from 20.1 to 22 cm.

SN-11,437 in 14 days. The fifth had received 2 gm when treatment was suspended. Before the onset of malaria this patient had a white blood count of 10,000 per cmm, polymorphonuclears 4,700. The total count fell to 3,700, polymorphonuclears 4,700. The total count fell to 3,700, polymorphonuclears 2,500, during clinical malaria. On the fourth day of drug administration polymorphonuclears numbered only 620 per cmm. At this point both drugs were discontinued and quinine was given to control malaria, a rapid return to normal counts followed. One other patient showed no unusual toxic symptoms during the 14-day course of treatment but later developed agranulocytosis. Seven days after discontinuance of drugs the white blood count was only 1,700, no polymorphonuclears were found. Energetic treatment for two weeks was necessary before the number of granulocytes reached normal levels.

Four volunteers without malaria were given sulphadiazine (5 gm the first day and 4 gm daily thereafter) concurrently with the two-week course of pentaquine and quinine. One of them developed agranulocytosis.

The concurrent administration of either paludrine or quinacrine caused a marked increase of pentaquine plasma concentrations. SN-11,437 caused a marked and sulphadiazine a moderate decrease of pentaquine plasma concentrations.

Quinacrine may increase the toxicity of pentaquine. Sulphadiazine therapy is potentially dangerous during the administration of pentaquine.

THIODET, J & FOURRIER, A. L'accès palustre, considéré comme un choc, peut-il être traité par des injections intradermiques de CO₂-globulines de paludéen (médication antichoc) [The Malarial Paroxysm considered as a Shock Phenomenon, its Treatment by Intradermic Injections of CO₂-globulin of the Malaria Patient (Anti-Shock Treatment)] *Bull et Mém Soc Méd Hôpît de Paris* 1948, Nos 26/27, 928-30

In 1937 THIODET and RIBÈRE showed that in acute attacks of malaria the relationship of serum albumin to serum globulin underwent variations comparable to those observed in serum supersensitiveness and other anaphylactic conditions. They reported at the same time a case of malaria in which the attacks were characterized not by fever but by urticaria. In subjects sensitized by an injection of therapeutic serum, the intradermal injections of CO₂-globulin prepared from the subject's own serum produces a series of small shocks analogous to those obtained by Besredka's method of desensitization. These considerations led to the treatment of four cases of *P. vivax* malaria with intradermal injections of CO₂-globulin prepared from the patient's serum. The treatment resulted in the suppression of rigor and fever although *P. vivax* continued its normal cycle in the blood stream. All four patients improved in health and put on weight, there was also an increase in the red cell counts. If these results are confirmed, this method of treatment may prove of value in pernicious attacks of acute malaria.

MALLIK K. L. B. Preventive Value of Paludrine in Malaria. *Indian Med. Gaz.* 1948, June v. 83 No. 6 271-2.

The residential area occupied by the Indian staff of the Ludlow Jute Mill in the Howrah District, contains eight families and a bachelors' mess and there amount to 47 adults and 39 children. The environment is highly malarious and during 1946 there were 65 malarial attacks—only two families escaped and 28 attacks occurred among the members of the bachelors' mess and its servants [from the context it appears that "attacks" is intended to imply individual cases]. Until the middle of 1947 quinine and quinacrine (mepacrine) were used for treatment and prophylaxis—the patients were not always regular in taking the drugs presented and relapses resulted.

In the second half of 1947 paludrine was introduced and a strict régime of prophylaxis was used. Adults and children over 10 were given 0.1 gm. twice a week and younger children had 0.05 gm. twice a week.

Those persons who had had fever within a month (mostly children) were initially treated with 0.3 gm. daily for 3 days although they had no fever at the time.

In 1947 there was no case of malaria among the families and the only 7 cases recorded occurred in the bachelors' mess. This latter finding is attributed to the fact that the members of the mess had neglected to take the second dose when they went home at week-ends. As the number of attacks in this group of 88 people was reduced from 65 in 1946 to 7 in 1947 and the latter cases are all believed to have been due to inadequate co-operation by the persons concerned, the author considers that the result of this small series substantiate the claim of paludrine as a causal prophylactic. The fact that paludrine was only introduced in the second half of the year must be taken into account in comparing the attacks during the whole of 1946 and the whole of 1947.]

DARCY T. M. W. Malaria and the Army. *J. Roy. Army Med. Corp.* 1948, July v. 91 No. 1 722-28. 27 rel.

This paper consists of a statement of the policy to be adopted in the control of malaria in the Army. As such it is doubly authentic and sets out a considered policy which is concerned with malaria survey, destruction of adult mosquitoes, prevention of breeding, the use of prophylactic drugs, method of personal protection and the siting of camps. It also outlines the method of training, and the responsibilities of particular individuals in the campaign such as Regimental Medical Officers and Hygiene Officers.

It is no reflection on the author who has also set out the facts to say that the picture is disappointing and does not reflect the enormous change which has taken place in malaria control in the last three years. The use of insecticides and those apparently only immediate ones is restricted to very minor place in the control of small outbreaks of malaria in which the cases are small, anything more serious calling for malaria survey and anti-malarial measures relying largely

on oil and paris green This is admittedly to be reinforced by an adult spraying campaign, but as it is apparently to be applied weekly it is not clear whether immediate or residual insecticides are to be used, or proper value gained from them Mepacrine is advised as a prophylactic drug and it is thought that it is still too early to form a definite opinion on the value of paludrine

The author rightly points to the disappearance of the wartime specialist malaria control service, though he over-estimates the extent of the disappearance, and pleads for the maintenance of framework on which expansion could occur in war

G Macdonald

SCHULTZ, K H Malaria Control carried out by UNRRA *Pub Health* Johannesburg 1948, June, v 12, No 6, 173-83, 3 graphs & 6 figs

This paper refers exclusively to work in Italy It consists of an account of the increase of malaria following war, and an historical account of control schemes organized to combat it. The organization and methods are described and illustrated, and there are some good histograms and graphs showing the success of work in different areas

PETTMAN, W E C Flushing Streams as an Antimalaria Measure under Field Service Conditions. *Indian J Malariology* 1947, Dec, v 1, No 4, 395-412, 13 figs

This paper is of real interest as it represents the hydraulic engineer's approach to the efficacy of flushing, not to the mechanics of siphons or sluices but to the relation between head of water, fall of stream and length of effective control The subject has been previously studied by WORTH & SULBRAHMANYAM [this *Bulletin*, 1941, v 38, 232], but deserves more enquiry

The author in Assam worked with simple dams and sluices, built in streams suited as breeding places for *Anopheles minimus*, and studied the shape and velocity of the wave at different distances from its origin He related these to the larvicidal effect of a single wave of known size and velocity, all

Showing effective range or distance below dam within which 95 per cent of larvae are killed for dams up to 4 ft high in streams whose fall is between 1 in 30 and 1 in 80

[Reproduced from the *Indian Journal of Malariology*]

three factors being obtained by direct measurement, and to the entomologist's assessment that a 95 per cent. kill by each individual was a produced perfect control. In consequence he was able to work out on engineering principles and direct confirmation by observation an effective range for flushes of different characters in different stream. The essential conclusions are epitomized in the figure here reproduced.

This figure omits reference to the effect of roughness of the stream bed, partly owing to the difficulty of measuring it and partly because it is a small factor that usually it makes no great difference in the type of stream considered. Observation of individual streams is however necessary to check that they are not grossly abnormal, before the formula can be applied.

The author rightly stresses that his observations apply only to breeding conditions for *A. minimus* in A. sam. They do however supply a rational approach of value to workers with this method in all countries.

HENDERSON J. M. The Eradication of *Anopheles albimanus* in Puerto Rico—
an Ecologic Discussion. *Mosquito News*, 1948 June & Sept. 8 Nos 2
& 3 45-9 87-101 [Refs. in footnotes.]

The author considers the tactics which should be adopted in a proposed effort to eradicate *Anopheles albimanus* from Porto Rico, an island of 354 square miles area of equable climate, with two million inhabitants and uniformly infested with this mosquito except on the mountainous central ridge.

The problem is both administrative and technological, only the latter aspect is discussed. The mosquito can be considered difficult to eradicate because its aquatic habit is very diverse including hoofmark and artificial containers. Its maximal flight range is great. It is more zoophilic than anthropophilic and never uses human habitations as daytime shelters commonly resting out-of-doors. On the other hand it does not hibernates there is no mechanism of prolonged survival of eggs away from water as in some species and it suffers a marked seasonal reduction from January to April which might facilitate eradication.

The mountain ridge in the island would make possible an attack on a relatively narrow front with the sea and mountains on the flanks so that in theory a progressive drive could be carried round the island though there would be difficulties due to the passage of transport through the area. A first operation. The author favours a main attack on larvae and on breeding places with a secondary attack on adults by means of residual insecticides. There are however so many unknown factors to estimate that it would be best to carry out a pilot scheme on a neighbouring smaller island of Vieques where precise data could be collected.

HART T. A. HART Jeanette H. & SARACHO-LOPEZ F. Malaria Control in
Guayaramerin, Bolivia. *Mosquito News*, 1949 Mar. 9 No. 1 1-5
7 figs.

Guayaramerin Bolivia, is an endemic malaria area with hot humid climate where the carrier has not been identified though six species of anophelins including *A. darlingi* are reported. Malaria control by application of par green to water and medication of the population with atabrine mepracrine has in the past had poor results. DDT in oil solution was applied to all houses in 1946 at an estimated dose of 1.43 gm. per sq. metre (5.8 oz. per 100 sq. ft.) and a second application of water soluble DDT at a dosage 1.43 gm. per sq. metre (5.8 oz. per 100 sq. ft.) was given later in the year. A similar

treatment was repeated in 1947. The results appear to have been excellent. In future, for reasons which are not quite clear, larvicidal treatment will be substituted.

The nature of the "water soluble DDT" is not defined. It does not appear from the context to be a suspension or emulsion. *G Macdonald*

KOISUMI, K & LIEN, Jih-Chung. Formosan Derris as an Anopheline Larvicide. *Chinese Rev Trop Med* 1948, Jan, v 1, No 1, 47-58

Derris is extensively cultivated in Formosa where it has been used for some time as an insecticide by agriculturists. During 1945, the authors investigated the value of derris as an anopheline larvicide using larvae of *Anopheles hyrcanus* var *sinensis*. As a diluent they used either powdered rice-straw or fine dry soil dust in various proportions.

To find the most suitable size of derris particle for use on water surfaces they screened the powders and grouped them into three grades: (a) large particles over 0.297 mm in diameter, (b) medium particles less than 0.297 mm, and (c) small particles less than 0.177 mm. Tests of these showed that in 72 hours the largest particle killed about 85 per cent of fourth stage larvae and only 44 per cent of first stage larvae. The medium particle killed 94 per cent fourth stage and 74 per cent first stage larvae. The smallest particle killed 56 per cent fourth stage and 100 per cent first stage larvae. It was decided that for field use the medium grade was the most satisfactory.

Experiments were then made with this grade of derris dust to determine the lowest quantity to apply to a given surface area of water. It was found that quantities between 0.05 and 0.3 gm derris dust per 3,300 sq cm of water surface gave kills ranging from 95 to 100 per cent in 72 hours. Field experiments subsequently showed that a rate of 0.2 gm derris per 3,300 sq cm of water surface was efficient.

A number of 24-hour experiments showed that toxicity to larvae was slightly greater at 18°C than at 14°C, that depth of water made little difference, that floating derris was more effective than the same quantity of powder stirred into the water and that soil dust as a diluent was satisfactory, and much less trouble than powdered rice-straw.

A warning is given that derris is toxic to fish, and that top minnows are killed if the proportion of powder to quantity of water is over 0.1 mgm per cent. *H S Leeson*

HAWKING, F & PERRY, W L M. Resistance to Proguanil (Paludrine) in a Mammalian Malaria Parasite (*Plasmodium cynomolgi*). *Lancet* 1948, Nov 27 850

Evidence has been given of acquired resistance by malarial parasites to plasmoquine (pamaquin), paludrine and quinine [this *Bulletin*, 1942, v 39, 438; 1943, v 40, 754; 1947, v 44, 969, 970; 1948, v 45, 158]. The present authors treated a baboon, infected by means of sporozoites of *P. cynomolgi*, with small doses of paludrine intramuscularly when the infection became patent. Partly as a result of drug treatment and the natural reactions of the host, parasites disappeared from the blood for considerable periods. Initially it was found that two daily doses of 0.03 mgm paludrine per kilo made the blood negative. After 14 months of repeated treatment with the small doses of the drug it was found in the case of the above animal that 23 to 30 mgm of paludrine, which approaches the maximum tolerated dosage, failed to free its blood of parasites. The acquired resistance thus appears to be very great. The infection in two other baboons and one rhesus monkey inoculated from the

rapidly depopulates at 6 per cent, the population is stationary and 3 per cent allows increase. The problem of increasing the numbers of cattle and pigs is still unsolved.

Sierra Leone.—The population is about 2½ million and there are probably less than 1,500 cases of sleeping sickness. epidemics have occurred near the French and Liberian borders but in 1943 the incidence there was about 1 per cent, and the epidemic is under control. observation is needed as the incidence is higher in the neighbouring countries. There are about 50,000–60,000 West African short-horn cattle which are believed to have a symptomless infection. improvement by selective breeding is therefore preferred to the introduction of outside breeds. About 8,000–8,000 are slaughtered annually. Tsetse flies occur almost everywhere and a large proportion are infected with animal trypanosomes.

The Gambia.—The area is about 4,000 square miles and the population about 250,000. No complete survey of sleeping sickness has been made but small surveys indicate an incidence of 1–8 per cent, some villages showing 25 per cent, or more. The co-operation of the French authorities is necessary to deal with the infection. The disease is mostly mild and chronic and spontaneous cures occur. Over-development of the groundnut industry is thought to have produced an increase of sleeping sickness owing to neglect of native food crops with malnutrition. cultivation of swamp rice in tsetse-infested areas is another factor.

There are about 70,000 West African short-horn cattle. symptomless trypanosomiasis exists but many cattle are thought to die of the disease.

The author concludes that trypanosomiasis is a fundamental barrier to progress in West Africa.

Species of trypanosomes.—The author believes that *T. panamense* is the only human trypanosome in West Africa, though atypical forms are found. see LESTER, this Bulletin 1934 v. 31 165. *T. rhodesi* and *T. congolense* are much commoner in cattle than *T. brucei*. In horses and donkeys the predominant species varies from place to place. *T. brucei* being commonest in some localities. camels have *T. brucei* only and it is the commonest species in pure tsetse fly epizootics of *T. simus* occur.

Diagnosis and Treatment.—A standard method of diagnosis (or at least of recording diagnosis) is needed. In Nigeria the Gold Coast and Sierra Leone a house-to-house census precedes mass diagnosis. gland palpation and puncture, blood examination, and lumbar puncture are used, the procedure varying according to circumstances. The author quotes interesting figures. in Nigeria (Bauchi province) gland juice alone 69 positive, gland juice and blood 4 blood alone 1. In the Gold Coast gland juice 129 blood alone 38. 1. were Leone gland examination mostly used but a census is not taken. in the Loma area, however, both gland juice and blood are examined. many symptomless cases occurred with trypanosomes in the blood only. Owing to staff shortage limited surveys only of animal trypanosomiasis in West Africa have been possible.

A standard treatment is desirable for unsupervised native staff. that commonly used in Nigeria, Sierra Leone and the Cameroons was three doses of Antrypol gm. 1 followed by five of trypanamide, gm. 2, at 5-day intervals. recently three doses of a mixture of Antrypol gm. 1 and trypanamide gm. 1 followed by two doses of trypanamide alone all at 5-day intervals has been used in Nigeria. it is shorter and seems to give better result. In the Gold Coast five doses of Antrypol gm. 1 are ordinarily given. late-stage patients may afterwards get ten doses of trypanamide gm. 1. or the course of trypanamide may be preceded by one dose only of Antrypol. Other courses and combinations have been tried. Pentamidine is thought to equal Antrypol in early cases.

Arsenophenylbutyric acid ("70 A") has given disappointing results in late cases in Nigeria and the Gold Coast

For cattle trypanosomiasis antimonyl sodium tartrate has been mostly used against *T vivax*, phenanthridinium chloride successfully against *T congolense* and *T vivax* and Antrypol against *T brucei*

Control—Mass survey and treatment has controlled sleeping sickness in all the British West African colonies and the incidence has been reduced below 2 per cent, but less is known about cure because patients are lost sight of, early cases are cured and late cases relapse. The French Sleeping Sickness Organization stated that mass treatment had eradicated the disease in the Cameroons and a similar result is claimed for a small area of the Belgian Congo near Lake Albert where the incidence was 10 per cent. The disadvantages in British colonies are that indefinite maintenance of sleeping sickness organization is necessary, the disease is not eradicated, and the problem of animal trypanosomiasis is unsolved

Special sleeping sickness dispensaries for treatment and local surveys are established in Nigeria, the Gold Coast and Sierra Leone, the staff are specially trained local inhabitants, in 1945 there were 40 dispensaries in Nigeria and staff were also posted to 19 Native Administration dispensaries, in the Gold Coast there are 9 sleeping sickness dispensaries but the dispensers do not travel, in Sierra Leone there are 6 sleeping sickness dispensaries and 5 rural treatment centres. In the Gambia there is no sleeping sickness service and patients are treated at the hospital and 6 Protectorate dispensaries

Prophylaxis by drugs—No conclusive results have been obtained in the colonies, in Nigeria Antrypol, gm 1 was tried but violent reactions and some deaths occurred, even with lower doses, and it was given up and pentamidine has been tried since, Antrypol was also tried in the Gambia without severe reactions, and in Sierra Leone Antrypol and tryparsamide, but the results are not yet known. A carefully controlled experiment with pentamidine was made in the Belgian Congo, a dose of 3 mgm per kgm being used, 721 people were protected for about 8 months. Unless the infection rate is high a large number must be treated prophylactically to obtain statistically significant results. In a laboratory experiment by van Hoof in the Belgian Congo three volunteers were protected for 6 months by a dose of pentamidine of 4.5 mgm per kgm. Van Hoof thinks that pentamidine is better than Antrypol as a prophylactic and that no cryptic infections follow its use

Defensive clearing—In the Gold Coast, Morris found that 500-800 yards of clearing along streams reduced *G palpalis* and *G tachinoides* by 60 per cent, $\frac{1}{2}$ mile by 80-95 per cent, 2-3 miles in the dry season and 5-7 miles in the rains gave 100 per cent reduction, 800-1,000 yards was the most efficient economically. If sufficiently large, as at Anchau in Nigeria clearing will eradicate tsetse fly in suitable areas, the cost is prohibitive in forest areas

Aggressive clearing—The aim is to extirpate the fly and it involves clearing all streams and rivers, it has been successfully done in the Anchau settlement in Nigeria and the Kumba valley in the Gold Coast. Cattle are also protected and since a cow needs 15 acres of grazing per annum in those countries, it is costly. A common policy of fly eradication is necessary in British and foreign West African territories

No practical results with DDT have yet been obtained

Organization of control in British West Africa—The Medical Department is in sole control of sleeping sickness measures in British West Africa and the Sudan, other Departments cooperate when needed. Formerly there was a Trypanosomiasis Committee of various Departments in the Northern Territories of the Gold Coast but it last met in 1937. In Nigeria a Developmental Committee of Divisions is proposed to coordinate the work of the various Departments

concerned. Coordination and development would be best obtained by a committee of Directors of Departments which would meet at least once a year the Governor would see that its decisions were carried out. An Inter-Colonial Sleeping Sickness Service has been proposed and the arguments for and against it are mentioned by the author who concludes that it is inadvisable, but a British Inter-Colonial Reclamation Service is desirable.

Anglo-Egyptian Sudan—Sleeping sickness in the northern Sudan is controlled by block clearings, concentration of people and treatment. In recent years there have been less than 100 cases a year and very few deaths. Mass surveys are made annually or more frequently patients are treated and report periodically and a pass system is used for visits to Uganda and the Belgian Congo. Antrypol is given prophylactically to such travellers and also to fly-boys and labourers exposed to tsetse flies. Clearings (800 x 20 yards) are made along streams and others around villages and watering places these have reduced fly movements by 75 per cent. Control measures cost £4000 per annum. No definite Sleeping Sickness Service exists.

French West Africa—The population in highly endemic centres is about 6 million, and 4½ million are surveyed annually. A special service of 4 European doctors, 38 *médicins auxiliaires* and 700 attendants makes these mass surveys with treatment and has full powers over the patients. They find a mixture of Moranyl (Antrypol) and trypanamide better than either drug alone in second-stage cases. pentamidine, 4-6 mgm. per kgm. is being tried intramuscularly and intrathecally. A case of apparently latent infection for over 4 years was seen by the author.

French Equatorial Africa—The figures of incidence are reliable only in the Brazzaville region (about 0.5 per cent.). A Special Sleeping Sickness Service lapsed during the recent World War and the present position of diagnosis and treatment is unsatisfactory but the incidence appears to be low (85-90 cases a year).

Belgian Congo—No special Sleeping Sickness Service exists. the disease is endemic in almost the whole of the western and southern parts. In 1940 the incidence in about 5 million examined was 0.4 per cent. The population is surveyed and treated twice a year. Aggressive clearing has not been done clearing being limited to watering places, fords and villages. Cattle are said to be in a state of premunition, the chief species of trypanosome being *T. uniformis*. There is an excellent laboratory at Leopoldville.

Liberia—The area is about 43,000 square miles and the population is thought to be between 800,000 (Dr. Bequaert) and 3½ million (Liberian Government). In the western areas in 1943-44 an incidence of 14.8 per cent. was found among 100,000 persons. In 1943-44 it was about 7.9 per cent. Mass treatment was given by the Firestone Plantation Company and the American Foundation of Tropical Medicine during these periods. In 1945 a United States Public Health Service Mission arrived to work for 5 years to care for the staff of certain public works. This Mission proposes to make a health survey which will include the endemic area of sleeping sickness. No information about keeping salivars in other areas of the territory exists.

NASH, T. A. M. *Tsetse Flies in British West Africa*. 77 pp. 15 folding maps & 82 figs. on 18 pls. 1943 & 1945. London. Published for the Colonial Office by H.M. Stationery Office. 21/10s.

This report was prepared for the Tsetse Fly and Trypanosomiasis Committee appointed by the Secretary of State for the Colonies. The author who has recorded many years of work in Nigeria made a ten month tour of the British West African Colonies and investigated all a part of the life of tsetse

Trypanosomiasis

Vol 46, No 3]

flies in relation to trypanosomiasis in man and domestic animals he discussed the subject with various Departmental Officers concerned—Administrative Medical Veterinary, Agricultural, Forestry and others, with other European residents, and with African chiefs and leading men. Much has been written about tsetse flies and trypanosomiasis in West Africa and this Report gives the views of many workers in those countries and a list of 100 publications. The author toured Nigeria from July 15th to November 3rd, 1945, the Gambia from November 7th to December 13th, 1945, Sierra Leone from December 13th, 1945 to February 21st to May 13th, 1946, and the Gold Coast from February 21st to May 13th, 1946, and collected an immense amount of facts and information which he has considered under various heads such as climate, vegetation, agriculture and trypanosomiasis of man and animals. The history of tsetse research in the colonies, the various species of tsetse flies and their distribution and habits, and the methods of control or eradication are dealt with in detail, each colony being treated separately, and finally, British West Africa is considered as a whole and in relation to neighbouring foreign territories. The history of tsetse for future research are offered. The Report is illustrated with 16 plates of photographs and 15 coloured maps. The maps show the climate, vegetation, distribution of species of tsetse flies, incidence of sleeping sickness, density of population and cattle areas. It is much too detailed to be abstracted and only some figures and other matters of interest can be mentioned in this review.

Nigeria—Area 372,671 sq miles. Dimensions 600 x 600 miles. Population over 20 million, averaging 55 per sq mile. Tsetse flies extend from the coast to 12° N (or further, along big rivers) and infest 79 per cent of the country, the only free areas being the Bamienda highlands in the Cameroons, the Jos plateau, and the Anchau corridor. The chief endemic areas total 110,000 sq miles (30 per cent). Cattle cannot be kept in 104,000 sq miles (28 per cent) because of trypanosomiasis, but infected zebu cattle are kept in 77,000 sq miles (21 per cent) and uninfected zebu cattle are kept in 77,000 sq miles (21 per cent) of tsetse-free country in the north. It is interesting that cattle cannot be kept in the southern part of Nigeria where sleeping sickness is rare but can be kept in the north where sleeping sickness is common.

The species of tsetse fly are *Glossina palpalis*, *G. morsitans* and *G. longipalpis*. The first occupies 54 per cent of Nigeria, the second 50 per cent, the third 9 per cent, and the fourth so far as is known a much smaller area in the south west of the colony. *G. palpalis* and *G. morsitans* live near rivers and streams and can be controlled in many areas by bush clearing, but *G. longipalpis* has a wide range and the only effective method of control is to increase the density of the population which drives away the wild game on which the fly depends for its food.

Possibly one-third of the 5 million cattle are infected with trypanosomiasis. The present cattle tax yields £375,000 per annum and the Veterinary Department spends also (other £70,000) per annum. The author suggests that the labour (cattle people) should be settled in reserves and that clearings be made annually to extend the grazing areas. The importance of "mechanical" measures is also mentioned. The importance of "mechanical" measures is also mentioned.

The vegetation in Nigeria and in West Africa generally changes from the coast towards the interior. At the coast are creeks and lagoons, mangroves, and then the inland evergreen forest is found next comes the bushy woodland savannah, and then the dry woodland savannah. The author suggests that the labour (cattle people) should be settled in reserves and that clearings be made annually to extend the grazing areas. The importance of "mechanical" measures is also mentioned.

crossing and around villages and community clearings where the people are turned out to protect their own villages are explained in the Report, and method prescribed. At Rukuba, west of Jos a suitable plan of clearing streams flow from tsetse flies 20 sq. miles with a population of 7,000 at a cost of £273. The methods of exterminating tsetse flies in Nigeria vary with the species and locality for *G. palpalis* and *G. tachinoides* in savannah woodland, partial clearing of riverine vegetation, together with "ruthless" barrier clearing, is effective but in the forest no method of extermination is known. *G. morsitans* has never been exterminated in Nigeria but the best method would be to control settlements in the area and encourage ruthless hunting of game for which ex-soldiers might be employed. A preliminary experiment could however be made.

Suggestions for future entomological research include a study of the ecology of *G. palpalis* and *G. tachinoides* in southern Nigeria and of *G. longipalpis* and *G. caliginosa*. Field experiments with DDT, study of direct transmission by other biting flies, tsetse surveys, tsetse behaviour, transmissibility of trypanosomes by various species of tsetse flies, the effect of dense thickets near villages on *G. palpalis*, various experiments with partial clearing and game destruction.

Gold Coast—Area 91,840 sq. miles, dimensions 400 x 230 miles, population nearly 4 million averaging 43 per sq. mile but in the Northern Territories 10 to 25 per sq. mile. Tsetse flies are present throughout almost the whole country. The chief sleeping sickness areas comprise 31,500 sq. miles or 37 per cent. of the country. The four species of tsetse flies of economic importance are *G. palpalis*, *G. tachinoides*, *G. morsitans* and *G. longipalpis*. *G. morsitans* is present but little is known about it. A few specimens were caught on the northern edge of the forest. *G. palpalis* occupies about 71,000 sq. miles (77 per cent.), *G. tachinoides* 47,000 (52 per cent.), *G. morsitans* 1,000 (23 per cent.), the first two species cover between them practically the whole of the Gold Coast. The economic importance of tsetse flies cannot yet be estimated owing to lack of data.

No complete sleeping sickness survey has been made but the general incidence is low. Zebu cattle cannot be kept except in the Accra plain and the north-east corner of the Northern Territories. Zebu cattle for slaughter are driven from the French territory on the north southward through the Gold Coast and by the time they reach Kumasi (Kumasi) 60 per cent. are infected with trypanosomes. There are about 228,000 dwarf cattle in the Northern Territories, they are tolerant of trypanosomiasis but are susceptible to *riverpest* and ant *riverpest* vaccination lowers their resistance to trypanosomiasis. The Veterinary Department breeds zebu x dwarf cattle crosses while the Agricultural Department aims at improving the dwarf cattle by select breeding. It is interesting that zebu cattle cannot live in the Gold Coast but can live in similar country in northern Nigeria, the difference is probably due to heavy infection of *G. morsitans* from game owing to the sparser population in the Gold Coast. The author suggests that different breeds of cattle from all parts of West Africa should be collected at Kono and subjected to infection to find the most resistant breed which would produce manure meat and milk under exposure to tsetse flies and poor grazing conditions.

The Forestry Department and the Sleeping Sickness Service don't agree about the position of forestry reserves and plantation evergreen belts belt and wind-breaks. Protective clearings for river crossings and around villages have been made and two large agricultural clearing one at Lawra in the north-west corner of the colony the other at Pung Tarnale were made the latter was a great achievement. It was done at a place where annual flooding of the river occurs and it freed 600 sq. miles from tsetse flies except at the height of the flood. Nearly 160 miles of river were cleared and the river bank at

now bordered with grass and there is no erosion. Building low weirs or dams of earth and stone was very successful and supplied 14 villages and 3,000 cattle with water in the dry season. A drawback is that the pools cause an increase in guineaworm infection, the weirs cost from £50 to £150 each. Clearings of the Kamba river system at Lawra were "ruthless" and eradicated *G. palpalis* and *G. tachinoides* from 105 miles of stream and 600 sq miles of country, stumping has led to erosion in some parts, and regrowth of *Mimosa asperata* in the river bed has permitted the return of *G. tachinoides*. Consolidation of the position by settling population has proved difficult, but an agricultural demonstration farm which is being set up should encourage settlement. The annual entomological expenditure in the Gold Coast is rather over £5,000.

The author comments adversely on the meteorological work, it is unreliable and there is a lack of care and interest. He suggests that a civil meteorologist with a European staff be appointed (at present it is under the Air Ministry) and that a Livingston atmometer be supplied to every station.

Suggestions for further research include fly surveys of Togoland and the Seni and Afram plains, finding the northern line of *G. longipalpis*, tsetse distribution (in all the colonies) should be shown on maps by symbols of Fly-Boy-Hour catches, initials of collector, month and year, and a negative symbol, effect on *G. palpalis* of felling around mining camps and towns in the forest, observations with marked flies at places of personal man-fly contact such as water-holes, and also on cattle routes.

Sierra Leone—Area 27,000 sq miles, dimensions [160×160 miles?], it extends inland for 170 miles and the greatest north to south distance is 200 miles, population over 1½ million averaging 66 per sq mile. The western half of the colony is flat, the eastern half mountainous except the coastal area. *G. palpalis* and *G. longipalpis* are the only important species of tsetse fly and *G. palpalis* alone transmits sleeping sickness and most of the trypanosomiasis of domestic animals, it occurs very sparsely throughout the whole country while *G. longipalpis* is found only in the extreme north, covering intermittently about 1,700 sq miles or 6 per cent of the country. *G. fuscus* is said still to occur on the northern frontier. The rainfall is very heavy, ranging from 188 inches on the Freetown Peninsula to 89 inches at Kabala in the north, and it falls mostly in a few months.

The vegetation comprises mangrove swamps in the coastal area of creeks, primary evergreen forest, secondary evergreen forest, transition from secondary evergreen forest to grassland, and grassland and orchard bush. The mangrove swamps are probably feeding grounds only of *G. palpalis* breeding taking place in the fringing dry ground areas. Extensive rice cultivation in some places has replaced the mangroves and fringing breeding grounds with eradication of *G. palpalis*, it is the ideal economic way of eradicating the flies but the mangroves could be left to prevent erosion. Much of the primary evergreen forest has been destroyed by native farming and although tsetse flies have been exterminated by it, the author thinks that the man-made erosion is a greater menace, the mountains are bare and the plains devastated. Secondary evergreen vegetation is also being destroyed by farming followed by too brief fallow periods, the author suggests that it should be preserved as a barrier to the spread of tsetse flies and to keep up the soil fertility. The transitional zone consists of tall grasses with blocks of evergreen shrubbery. In the northern half of the territory are grassland and orchard bush which allow farming with short fallow periods. *G. palpalis* is here found along the streams as well as along the rivers.

There are two main sleeping sickness areas. (1) Sherbro Island and (2) south-eastern Konno. Luawa and Kissi, altogether about 2,800 sq miles or 10 per cent of the whole country. The incidence on Sherbro Island is very low,

crossing and around villages and community clearings where the people are turned out to protect their own villages are explained in the Report and methods prescribed. At Rakuba, west of Jos, a suitable plan of clearing streams freed from tsetse flies 20 sq miles with a population of 7 000 at a cost of £273. The methods of exterminating tsetse flies in Nigeria vary with the species and locality for *G. palpalis* and *G. tachinoides* in savannah woodland, partial clearing of riverine vegetation, together with "ruthless" barrier clearing is effective but in the forest no method of extermination is known. *G. morsitans* has never been exterminated in Nigeria but the best method would be to make controlled settlement in the area and encourage ruthless hunting of game for which ex-soldiers might be employed a preliminary experiment would however be made.

Suggestions for future entomological research include a study of the ecology of *G. palpalis* and *G. tachinoides* in southern Nigeria and of *C. longipalpis* and *G. californica* field experiments with DDT study of direct transmission by other biting flies, tsetse surveys, tsetse behaviour transmissibility of trypanosomes by various species of tsetse flies the effect of dense thicket near villages on *G. palpalis* various experiments with partial clearing and game destruction.

Gold Coast—Area 91,840 sq miles dimensions 400 x 230 miles population nearly 4 million averaging 43 per sq mile but in the Northern Territories 10 to 25 per sq mile. Tsetse flies are present throughout almost the whole country. The chief sleeping sickness areas comprise 34,500 sq miles or 37 per cent. of the country. The four species of tsetse flies of economic importance are *G. palpalis*, *G. tachinoides*, *G. morsitans* and *G. longipalpis*. *C. ugrofascia* is present but little is known about it a few specimens were caught on the northern edge of the forest. *G. palpalis* occupies about 71,000 sq miles (77 per cent.) *G. tachinoides* 47,000 (51 per cent.) *G. morsitans* 1 000 (2½ per cent.) the first two species cover between them practically the whole of the Gold Coast. The economic importance of tsetse flies cannot yet be estimated owing to lack of data.

No complete sleeping sickness survey has been made but the general incidence is low. Zebu cattle cannot be kept except in the Accra plain and the northern corner of the Northern Territories. Zebu cattle for slaughter are driven from the French territory on the north southward through the Gold Coast and by the time they reach Kumasi (Ashanti) 80 per cent. are infected with trypanosomes. There are about 228 000 dwarf cattle in the Northern Territories. They are tolerant of trypanosomiasis but are susceptible to rinderpest and under pest vaccination lowers their resistance to trypanosomiasis. The Veterinary Department breed zebu x dwarf cattle crosses while the Agricultural Department aims at improving the dwarf cattle by zebu breeding. It is interesting that zebu cattle cannot live in the Gold Coast but can live in similar country in northern Nigeria. The difference is probably due to the heavy infection of *G. morsitans* from game owing to the larger population in the Gold Coast. The author suggests that different breeds of cattle from all parts of West Africa should be collected at Vom and subjected to insecticide to find the most resistant breed which would produce manure more and milk under exposure to tsetse flies and poor grazing conditions.

The Forestry Department and the Sleeping Sickness Service should agree about the position of forestry reserves and plantation evergreen belt and wind-breaks. Protective clearings at river crossings and around villages have been made and two large areas cleared—one at Lawa in the north-west corner of the colony the other at Poni. Yamalo were made the latter was a great achievement as it was done in a place where annual flooding of the river occurs and it freed 600 sq miles from tsetse flies except at the lower bit of the flood—nearly 160 miles of river were cleared and the river bank.

now bordered with grass and there is no erosion. Building low weirs or dams of earth and stone was very successful and supplied 14 villages and 3,000 cattle with water in the dry season. A drawback is that the pools cause an increase in ginn worm infection, the weirs cost from £50 to £150 each. Clearings of the Kumba river system at Lawra were "ruthless" and eradicated *G. palpalis* and *G. tachinoides* from 105 miles of stream and 600 sq. miles of country, stumping has led to erosion in some parts and regrowth of *Mimosa asperata* in the river bed has permitted the return of *G. tachinoides*. Consolidation of the position by settling population has proved difficult, but an agricultural demonstration farm which is being set up should encourage settlement. The annual entomological expenditure in the Gold Coast is rather over £5,000.

The author comments adversely on the meteorological work—it is unreliable and there is a lack of care and interest. He suggests that a civil meteorologist with a European staff be appointed (at present it is under the Air Ministry) and that a Livingston atmometer be supplied to every station.

Suggestions for further research include: fly surveys of Togoland and the Sen and Mram plains; finding the northern line of *G. longipalpis* tsetse distribution (in all the colonies) should be shown on maps by symbols of fly, Box-Hour catch, initials of collector, month and year, and a negative symbol; effect on *G. palpalis* of felling around mining camps and towns in the forest; observations with marked flies at places of personal man-fly contact such as water-holes, and also on cattle routes.

Sierra Leone—Area 27,000 sq. miles (dimensions 160 x 160 miles?), it extends inland for 170 miles and the greatest north to south distance is 200 miles; population over 1½ million averaging 66 per sq. mile. The western half of the colony is flat, the eastern half mountainous except the coastal area. *G. palpalis* and *G. longipalpis* are the only important species of tsetse fly and *G. palpalis* alone transmits sleeping sickness and most of the trypanosomiasis of domestic animals. It occurs very sparsely throughout the whole country while *G. longipalpis* is found only in the extreme north covering intermittently about 1,700 sq. miles or 6 per cent of the country. *G. fusca* is said still to occur on the northern frontier. The rainfall is very heavy, ranging from 188 inches on the Freetown Peninsula to 87 inches at Khabala in the north, and it falls mostly in a few months.

mostly less than 2 per cent. The trading town of Bonthe is visited by infected Africans from the other sleeping sickness area. It is interesting that there have been 5 cases of sleeping sickness in Europeans in 4 years. They travel mostly by launch and may have been infected mechanically from the native crew. A other biting flies swarm at times in the creeks. Information on the incidence among the crews would be interesting. In the eastern area, bordering French Guinea and Liberia, incidence rates of up to 20 per cent were found in 1941 although tsetse flies were scarce. It was quickly controlled by mass treatment and in 1945 the incidence was less than 1 per cent. The author thinks that increased rice-growing from 1941 may have helped to reduce the incidence. In 1941, cases with few symptoms but with heavy blood infection were found [see this *Bulletin* 1948: 1: 45-410]. The author suggests that rapid mass prophylaxis at the beginning of the hot weather would reduce infection of flies from undiagnosed cases as the life of tsetse flies is shortest in the hot weather. Experimental clearing in the area should be done as a guide to the best kind of clearing to be undertaken. Clearing followed by rice cultivation might be both effective and economically valuable.

Trypanosomes kill horses and donkeys but few cattle. Infection of cattle in the northern areas, however, may be more fatal as in one part there were in 1942, only about 100 cattle in 800 sq. miles. Sierra Leone might become the greatest stock raising country in West Africa. *G. morsitans* is absent and *G. longipalpis* in a small area and unlikely to spread. Dry season grazing is good. Rinderpest is unknown and there is an enormous area of grassland. On the other hand, pleuropneumonia is present but could be combated by vaccination, contagious abortion is reported to exist and only certain tribes (4-6 per cent. of the population) keep cattle. In 1942 there were lost 45,000 cattle.

The policy of the Agricultural Department is to encourage swamp rice growing and discourage upland rice growing and this would allow longer fallow periods and lead to decrease in the numbers of tsetse flies. The Forestry Department wish to increase the forest reserves by cultivation of trees in the upland. Cash tree crops such as timber, cocoa, oil palm, citrus and rubber can be grown.

The author's suggestions for future entomological research include an inquiry into the effect of wet mud on pupae, the life history of tsetse and rates of infection, the influence of pig keeping and surveys of the distribution of *G. longipalpis*.

The Gambia—Area 4,130 sq. miles, dimensioned about 300 miles long by an average width of 6 miles. It extends along both banks of the River Gambi. It lies in north latitude 13° 30' which is about that of the northern boundary of Nigeria and has a similar climate and vegetation. Population 220,000, at a average density of 53 per sq. mile but if 1,000 sq. miles are omitted the density is 48 per sq. mile. Tsetse flies—*G. morsitans* and *G. longipalpis*—are both at present throughout the former confined to the sandstone plateau country and the latter to the river and creek and each species could be controlled separately. The author thinks that there are no ticks, although *Im. papillipes* may be present in the South Bank Province. Two oil palm forests near the mouth of the river also harbor *G. longipalpis*. The people must be warned from the tsetse-infested river banks and have excellent well cattle can be kept in all the provinces. *G. morsitans* is present throughout the north bank, but only on the south bank there are two reserves where it has not been found since the lower part 50 miles and the other for about 45 miles near the northern end. No entomological survey has been made since 1911.

Mangroves extend up the river for 160 miles then there is a swamp forest for 34 miles and finally 105 miles of river with light land in the dry season. Sea water penetrates up the river for 100 miles. The Niger is a tidal clearing technique would almost certainly succeed in eliminating *G. longipalpis* but attempt to eliminate *G. morsitans* by clearing would be wasteful.

much of the higher land is uncultivable so *G morsitans* could not be dealt with by increasing the density of the population. There are few antelopes and *G morsitans* probably feeds chiefly on baboons. The author distinguishes "close personal" and "close impersonal" contact between man and tsetse fly, the former occurs at village water-holes where the same people are repeatedly exposed to bites, the latter on the river (*G palpalis*) and roads (*G morsitans*) where exposure is more casual and the flies feed on many kinds of hosts. In the Gambia contact is impersonal as the people use wells except in the creeks.

There are about 70,000 cattle of two kinds, true West African shorthorn dwarf, and crosses of these with N'dama descendants of the Hamatic longhorn, both are very resistant to trypanosomiasis but not to rinderpest. A cross, with zebu cattle, is called Gobira and is more resistant to rinderpest. The common trypanosomes are *T congolense* and *T vivax*, *T brucei* being rare, calves often recover spontaneously. The cattle live exposed to *G morsitans* but if the flies feed mostly on baboons, they will not be heavily infected, in the Niuni area cattle do badly probably because there is more game there and the flies would be more heavily infected. Since the anti-rinderpest campaign began cattle have increased from 35,000 to 70,000.

The author's suggestions for future research include fly surveys of eastern Niuni and the high-banked reaches of the upper river, feeding of *G morsitans* on baboons, a sleeping sickness survey of the Gambia to determine the relative importance of the two species of tsetse fly and for plans to be made to deal with the worst areas.

West Africa—In a general summary the author has included on two maps of West Africa the latest data for the French and Portuguese colonies, he notes that the French map (*Carte de Repartition des Glossines et d'installation des Chantiers Prophylaxie Agronomique*, 1942) differs considerably from earlier maps and mentions the chief differences.

Where the West African coast line is at right-angles to the south-west monsoon (French Guinea to Liberia, west Gold Coast and Nigeria) the rainfall is heavy on the coast and decreases steadily inland until near the desert there are eight dry months and less than 30 inches of rain, but where the coast lies parallel with the south-west monsoon the dry conditions of the interior extend to the sea where however, the humidity is greater than in the interior. The length of the dry season increases on going northward along the Atlantic seaboard.

The author summarizes for West Africa the various aspects dealt with in the individual colonies. In his general conclusions he states that "the whole subject of man-fly contact needs investigation by a team of doctors, entomologists and statisticians" other conclusions are that study of the effect on tsetse of altering the plant succession should be made by large-scale field experiments and the effect on cattle of a certain amount of game destruction in an area without attempting tsetse eradication should be investigated.

NASH T. A. M. The Anchau Rural Development and Settlement Scheme
22 pp 10 figs (3 folding) & 16 figs on 4 pls 1948 London Published
for the Colonial Office by H. M. Stationery Office [3s 6d]

The Anchau Settlement is an area of 712 square miles in the form of a corridor 70 miles long by about 10 miles wide, situated in the eastern part of Zaria Province of Nigeria and extending in a south-easterly direction from the Kano-Zaria section of the main railway, it is traversed throughout its length by the River Galma and along its south-western side runs the Zaria-Jos railway, a few miles away but touching the corridor at two points. The corridor lies in

four Districts of Zaria Province—eastern Makarfi Ikara, Anchari, and Kofara from north-west to south-east. It was chosen as an area to be freed from tsetse flies and developed as a settlement.

The Settlement Scheme arose from the need to deal with a high incidence of sleeping sickness causing a serious mortality and the opportunity was taken to improve hygienic living and working conditions, and social amenities without attempting to alter the habit and daily life of the people. This area was chosen after much preliminary investigation, including a census of the people, entomological, vegetational and agricultural surveys, and estimates of the requirements and supplies of water, fuel and other needs.

The seriousness of sleeping sickness was observed in 1894 and in 1896 the author suggested the choice of the Anchari corridor as it had good communications and the eradication of the tsetse flies seemed to be possible. The Scheme was approved by the Secretary of State for the Colonies and a sum of £95,000 was granted from the Colonial Development Fund on condition that economic development should be an essential feature. It was to be spent in five years but the World War caused an extension to ten years. The work was carried out by the Sleeping Sickness Service directed by Dr H. M. O. Lester and the author was the senior entomologist on the Staff.

People living in adjacent areas were moved into the corridor to increase the population enough (to 70 per square mile) to maintain the bush-clearing by re-slashing along the streams. The only species of tsetse flies present were *Glossina palpalis* and *G. tachinoides* which keep near the streams and the bush-clearing was therefore less difficult than if *C. morsitans* had been present. High trees were not felled except at the end of the clearings where complete "ruthless" clearing for a mile of stream, as the crow flies, was necessary to prevent tsetse flies from re-entering during the rainy season. Details of this clearing are given in the author's paper *Tsetse Flies in British West Africa 1948* H.M.S.O. [above].

The preliminary work was begun in October 1937 and the building of new villages and hamlets began in 1939: the people built the huts they were used to but to a standard plan of blocks of compounds separated by fire-lanes around a central well which was 80 yards distant from the nearest pit latrine. Each compound was 100 feet square (or 100 × 50 feet) and contained on the average 7.5 persons: each block was separated from others by a fire-lane of 1.5 feet (diagrams of a village of 60 compounds and of a compound of 11 huts are given). Huts were 12 feet across and 12 feet from the nearest neighbouring hut. Pit latrines were made in the compound.

Wells of standard pattern were 4 feet across, cement lined and the mouth had a cement collar 2 feet high with a bevelled edge and a wooden roller to facilitate drawing: the water was poured from the bucket into cement basins from which it ran through pipes into the people's water casks. A special cement pump with a drain prevented too much mud from forming around the well. In September 1945 there were 128 standard wells in the corridor. Old sanitary wells were filled in or converted into pit latrines and public wells in the compound had a simple cement top fixed for which the owner paid 10/-.

Fuel—The average consumption of wood-fuel per head was 15 cwt (2 cords) per annum: on an acre of the local wooded country would supply 17 persons for year, so 12 acres would be needed for a 12-year cutting rotation.

Takalsiya ("walk in health") is the name of a new town built about 1 mile from the town of Anchari and into which some 1,000 of the inhabitants of the old town of Anchari were moved. It is the centre of local government and has a dispensary, school, mosque, court-house and prison. There is a new market with 14 stalls and a slaughter slab and a well, also an animal clinic, a clarified butter-fat unit and a hide-drying enclosure. The road is 160 feet

wide and are planted with avenues of mango, fig, and Cassia trees. The attendance on market-day was over 7,000.

Other improvements effected were hygienic improvements in the old town of Anchau and other small towns, issue of 18,500 fruit trees, introduction of new crops for trial, issue of ploughs and ploughing oxen, a rinderpest immunization camp, pig-keeping, breeding of horses and donkeys and of good strains of goats and poultry were encouraged. Communal forestry areas and forest reserves were established, elementary and village schools were set up, where reading in Hausa and the Mohammedan religion were taught.

Anti-tsetse stream-clearing—By April, 1945, tsetse flies had been eradicated from 610 square miles by clearing 540 linear miles of stream, and 50,000 people lived in fly-free country.

Costs—Huts, 21s each, wells, £40 each (37 feet deep), market stalls, £40 each, slaughter slab, £40, clearing (540 miles) £11 per mile for 450 miles, when wages were 4d per day.

Future prospects—The Native Authority needs training and could not yet take over the management of the area from the Europeans, without continuous supervision it would relapse, so the Sleeping Sickness Service should continue in control until a full-time District Officer can be appointed. The author makes useful suggestions for similar projects from the lessons learnt in this one, one being that an aeroplane should be used in surveying.

The Anchau Scheme has been the subject of previous papers [this *Bulletin*, 1939, v 36, 672, 736, 1942, v 39, 241, 1945, v 42, 788, 1946, v 43, 1022, 1947, v 44, 971], but this is the first detailed account of the work done during the eight years from 1937 to 1945 and it will be very useful as well as interesting to all who are engaged in combating trypanosomiasis not only in man but also in domestic animals, which is regarded by some as the more important disease. Excellent photographs, plans and maps illustrate the paper. J F Corson

BUXTON, P. A. *Trypanosomiasis in Eastern Africa, 1947*. 44 pp. 1948.
London. Published for the Colonial Office by H M Stationery Office
[3s.]

This comprehensive report to the Tsetse Fly and Trypanosomiasis Committee in London is based on the author's visits in 1945 and 1946 to nearly all the African countries where trypanosomiasis is transmitted by tsetse flies, he attended conferences, visited and had discussions with various workers and inspected many areas where control of trypanosomiasis and tsetse flies, and reclamation of land for settlement, farming and grazing, had been carried out. The subject is so large and has so many aspects that it was necessary to select the most important and less well-established matters with special reference to work now being carried on. The report is both appreciative and critical of past and present work and several important recommendations are made. The need for more intercourse between workers through conferences, committees, exchange of visits and other forms of communication and discussion is strongly emphasized [work on trypanosomiasis has been greatly hampered by two World Wars and a period of world-wide financial depression].

The author groups his observations under the following heads: Current Problems and Research, Methods of Reclamation from Tsetse, Results of Reclamation, Organization of Research and Reclamation, and concludes with a four-page Summary. The whole subject is dealt with in considerable detail under subheads but the author has naturally had to select the more interesting and important features and matters which have not been sufficiently

appreciated. Some of these are given here though necessarily in a compressed and somewhat disconnected form.

Entomological Problems and Research.—The Tsetse Committee should prepare a uniform map for Eastern Africa on a scale of 1/4 000 000 within the next two years. The nomenclature of plant associations and types of woods, vegetation needs revision and standardization. It would be useful to know whether advance of tsetse flies follows an increase in their number. It should be remembered that advances are more noticeable than retreats and that both have no doubt occurred. Referring to the cost of the work at Shinyanga (Tanganyika Territory) during the last 25 years, the author points out that reclamation of land is not the only benefit obtained—a great deal of knowledge of tsetse flies has been acquired which will be a valuable foundation for future work. More attention should be given by entomologists to the transmission of trypanosomes by tsetse flies. An important question is whether the association of tsetse flies with certain types of vegetation depends on their perception of climatic conditions or on the smell and appearance of the vegetation. A young scientist with special knowledge of insect behaviour should visit Africa to study the question for 3 years. Direct or mechanical transmission of trypanosomes by tsetse flies and other blood-sucking flies needs further study. The authorities of the British Museum (Natural History) should be asked to compile a monograph on the Tabanidae. The precipitin test is useful to determine on which animals tsetse flies feed, but standard sera should be prepared in a large serological institute in Europe to ensure accuracy. Nocturnal feeding by tsetse flies should be investigated by means of an infra-red projector and a lens. The physiology of digestion in tsetse flies needs further study. It is remarkable that usually only a small percentage of flies which have fed on blood containing trypanosomes become infected—the case of the mongli reed-bark which may infect at least 60 per cent. of surviving flies is an interesting exception, and this should be investigated as well as the influence of temperature on the speed of development of the trypanosomes in the fly.

Protocols Problems and Research.—Interesting work on the morphology of trypanosomes has again raised the question of sexual differentiation and multiplication of trypanosomes. The author thinks that recent work tends to emphasize the distinctness of *T. rhodesiensis* and *T. brucei*.

Problems and Research in Human Medicine.—The importance of human trypanosomiasis may be estimated to some extent by the incidence and mortality in Kenya, Uganda and Tanganyika Territory less than 1000 cases and about 300 deaths a year are noticed and about 100 cases with 10-20 deaths a year in Northern and Southern Rhodesia, Nyasaland and Namaland. These numbers are small though there is of course always the possibility of an epidemic occurring. An interesting fact in epidemiology is the existence of healthy human carriers of trypanosomes. Another subject that has been much discussed is the animal reservoir of human trypanosomes, especially the wild animal reservoir. The author notes that it has been recommended that a medical man should concentrate on the epidemiology of sleeping sickness and make suggestions regarding its survey of large areas and when work in a small selected area should be undertaken the latter being an area where mild Gambian sleeping sickness occurs and this should be observed for a long period without the use of curative drugs to see whether spontaneous recovery takes place (is there not some risk to life). The author thinks that persons exposed to special risk of infection should receive prophylactic injections of antitrypanin every 3 months. The reviewer would prefer the greater risk of getting an unmodulated infection to the lesser risk of getting a marked infection.

Problems and Research in Veterinary Medicine.—There are said to be about 14 million cattle and about 15 million people in the East African colonies. It

believe that this transformation has actually taken place in the past and may occasionally recur under exceptionally favourable conditions.

In the case of Chagas's disease the rôle of lower mammal as reservoir host is much clearer. American human trypanosomiasis is a typical zoonosis, i.e. primarily an infection of wild animal (such as armadillos) from which it

dogs, also acquire the infection and serve as reservoir hosts. The position in the United States is peculiar for human trypanosomiasis has not hitherto been recorded there though local wild rat and *Triatoma* bugs harbour *T. cruzi* which is infective to man under experimental conditions.

Dr J. T. EDWARDS drew attention to the peculiarities of the veterinary aspects of trypanosomiasis which were caused by trypanosomes belonging to three groups (*brucei*, *congolense* etc.) differing in their morphology, development and antigenic constitution, as well as in response to drug treatment. In the case of infection with *T. cruzi* there was a difference in the response of various species of domestic animals to therapeutic and preventive treatment especially with Naganol. While in horses only large doses of this drug were effective in the case of bovines smaller doses of simpler remedies produced the desired effect. Dogs and camels occupied an intermediate position with regard to response to chemotherapy.

Dr Edwards then turned to the inter-relationship of trypanosomes of the *brucei* group. Indirect proof of their close affinity is provided by the successful employment of antigens prepared from *T. brucei* and *T. cruzi* in the complement fixation test for Dourine. As regard the possible adaptation of *T. brucei* to man, a parallel is provided by *T. equiperdum*. This species is usually not transmissible to rats but some strains are infective and can be passed through a series of these animals in which the course of infection is indistinguishable from that caused by *T. brucei* and *T. cruzi*.

Brig J. S. H. BURN thought that the prospect of discovering a drug conferring protection against *T. congolense* infection was promising especially in view of the encouraging result obtained with phenanthrodimine. This view was supported by Dr E. M. LOURIE who also remarked that the interpretation of many epidemiological problems in trypanosomiasis suffer from a tendency to regard the characters of the trypanosomes as being fixed. Actually it was possible to enhance the virulence of *T. gambiense* to that of *T. brucei* by passage through sucking rats. It has also been shown that the virulence of *T. rhodesiense* for man is considerably reduced after prolonged passage through sheep. In the light of these facts it is possible that tsetse which at the beginning of this century produced an epidemic form of sleeping sickness in Uganda, has assumed their present benign form after many years in game animals.

Dr I. HAWKING noted that since bovine and human trypanosomiasis in Africa originated from wild game control of the disease depended upon control of the reservoir host which need not in all cases destroy wild game. However Dr P. L. LE ROUX cited examples in favour of destruction of game for the eradication of tsetse. He also drew attention to the possible influence on the epidemiology of trypanosomiasis of temperature which has a direct effect on the infection rate of tsetse flies. Actually in the Rhodesias and in Bechuanaland sleeping sickness is restricted to the hottest areas.

Dr L. A. H. ADE, in reply mentioned the example of *T. vivax* a tsetse-borne infection which has spread far outside Africa into countries where it is transmitted by Tabanid flies. He said that evidence of common antigen in trypanosomes of the *brucei* group has also been provided by an blood and referred to recent physiological researches suggesting that the metabolic

processes in various groups of trypanosomes may be correlated with differences in their response to chemotherapy. He also stated that the clinical manifestations due to *T. gambiense* and *T. rhodesiense* were not clearly demarcated.

HEISCH, R B. Rhodesian Sleeping Sickness in Kenya Colony. *J Trop Med & Hyg* 1948, Nov, v 51, No 11, 225-7

Two cases of sleeping sickness, one African, one European, were observed in 1947 in the south-west corner of Kenya, near the Tanganyika border. The diagnosis was made on (a) the acute course of the disease and (b) the virulent nature of the infection in subinoculated white rats in whose blood posterior nuclear trypanosomes occurred to the extent of 2-10 per cent of the total organisms. Monkeys (*Cercopithecus aethiops*) were easily infected, also guinea-pigs which proved the most convenient animals for maintaining the strain. Baboons were completely refractory, and the serum of these animals was found to exert a protective action on rats suffering from the disease though failing to cure them completely.

The blood of 82 local Africans and of 4 antelopes was examined but no trypanosomes were found. One cow showed *T. vivax* in its blood. Approximately 500 locally caught *Glossina swynnertoni* were allowed to bite 8 rats. One of these rats subsequently developed a *T. congolense* infection while three showed polymorphic trypanosomes. The latter were inoculated into a human volunteer with negative results and the trypanosome was therefore presumed to be *T. brucei*.

Laboratory-bred *G. swynnertoni* and *G. palpalis* were fed on animals infected from the European case. 11.4 per cent of the former and 2.3 per cent of the latter species of fly became infected. The prevalent tsetse flies of the district were *G. swynnertoni*, *G. pallidipes*, *G. fuscipleuris* and *G. brevipalpis*. [The author observes that the only definite record of Rhodesian sleeping sickness in Kenya Colony was in 1942, when a few Africans were affected by an extension of an epidemic from Uganda.]

STRUGGER, S. Fluorescence Microscope Examination of Trypanosomes in Blood. *Canadian J Res Sect E Med Sci* 1948, Aug, v 26, No 4, 229-31, 1 pl

The author describes two fluorescence microscope methods for the detection of trypanosomes in scanty infections.

The author had previously demonstrated that acridinorange (3, 6-tetramethyldiaminoacridin) was a vital stain for protoplasm, and has now applied it for selective staining of living trypanosomes in the blood. A drop of blood is mixed with a drop of acridinorange solution (1 in 10,000 of 0.85 per cent NaCl) on a slide and examined under a coverslip with a blue light fluorescence microscope. The apparatus can be constructed as follows: the source of light is provided by a carbon-arc lamp with attached convex lens, producing a bundle of parallel rays, which are filtered by a cuvette (2.5 cm thick) filled with a solution of saturated copper oxide ammonia to allow only blue light to reach the plane mirror of the microscope. The latter is of the ordinary type but has an orange-coloured filter inserted over the ocular, in order to absorb blue light.

When a fresh blood preparation is examined under low power of the microscope, the red cells are almost invisible, but the leucocytes are vitally stained, their nuclei and cytoplasm having a strong green fluorescence enabling an accurate count of the leucocytes to be made. The trypanosomes exhibit a

STRUGGER, S. Fluorescence Microscope Examination of Trypanosomes in Blood. *Canadian J Res Sect E Med Sci* 1948, Aug, v 26, No 4, 229-31, 1 pl

The author describes two fluorescence microscope methods for the detection of trypanosomes in scanty infections.

The author had previously demonstrated that acridinorange (3, 6-tetramethyldiaminoacridin) was a vital stain for protoplasm, and has now applied it for selective staining of living trypanosomes in the blood. A drop of blood is mixed with a drop of acridinorange solution (1 in 10,000 of 0.85 per cent NaCl) on a slide and examined under a coverslip with a blue light fluorescence microscope. The apparatus can be constructed as follows: the source of light is provided by a carbon-arc lamp with attached convex lens, producing a bundle of parallel rays, which are filtered by a cuvette (2.5 cm thick) filled with a solution of saturated copper oxide ammonia to allow only blue light to reach the plane mirror of the microscope. The latter is of the ordinary type but has an orange-coloured filter inserted over the ocular, in order to absorb blue light.

When a fresh blood preparation is examined under low power of the microscope, the red cells are almost invisible, but the leucocytes are vitally stained, their nuclei and cytoplasm having a strong green fluorescence enabling an accurate count of the leucocytes to be made. The trypanosomes exhibit a

November 1946	Treated group 3 cases diagnosed clinically and on cerebrospinal fluid changes (no trypanosomes seen in blood or gland) Control group 7 new cases (trypanosomes seen)
June 1947	Treated group 3 cases diagnosed clinically and on cerebrospinal fluid changes, with no trypanosomes seen in blood or gland and 1 in which trypanosomes were seen. Control group 3 new cases (trypanosomes seen).

In summary among 133 treated persons only 1 new case was found with trypanosomes by the end of the two-year period though there was strong evidence of a high incidence of cryptic infections. Among 419 control there were 23 new cases all with trypanosomes. A 15-month interval between injections is judged to be too long.

(6) The Kintswana area (population 3600) consisted of 23 villages. One of these was selected as the "geographical and endemic centre of the area and after full curative treatment of those recognized to be infected, the remaining inhabitants (705) were treated prophylactically. The other 22 villages served as controls. Prophylactic treatment consisted of only a single injection of propamidine. Progress of the investigation was as follows (Treated group again refers only to those treated prophylactically) —

August, 1945.	Treatment
January 1946.	Treated group no new cases. Control group 54 new cases (trypanosomes seen)
May 1946.	Treated group 183 persons lumbar punctured and 11 per cent. found to have increased cell-counts.
August, 1946.	Treated group no new cases. Control group 39 new cases (trypanosomes seen)
January 1947	Treated group no new cases. Control group 49 new cases (trypanosomes seen)

Here also there was striking evidence of the "sterilizing" effect on the blood and lymphatic system combined with strong indication of cryptic infections when lumbar puncture was performed. In the authors' opinion any alteration in the cerebrospinal fluid, in these two areas is attributable to keeping sickens since relapsing fever does not occur and syphilis is very rare.

[This is a valuable contribution representing field trials of the prophylactic properties of diamidines on a really impressive scale conducted under the auspices of the FORCANT (see this Bulletin, 1948, 45:816). It is also the first time that the complication of cryptic infection has been clearly illustrated in field prophylactic work with diamidines.

In discussion, V. H. HOF suggested that many of the people with cryptic infection might have become infected before rather than after the prophylactic treatment. FARE did not think that this could apply to a high proportion of these cases especially those in whom the cerebrospinal fluid was only slightly altered toward the end of the two-year period. V. H. HOF also thought that cell-counts without protein estimations of the cerebrospinal fluid are inadequate since certain (unnamed) observers in the Belgian Congo believe that a moderate increase in cells (up to 100 per cmm) without increased protein may occur in Africans who appear quite healthy or who may be suffering from trivial conditions such as a pruriginous dermatosis.

CHOUZ AFKS F. Contribution à l'étude de l'action des ultrasons sur les hématies [Effect of Ultrasonic Waves on Red Blood Corpuscles]. *R Soc Biol.* 1948, Aug. 14th Nos. 15-16 1080-82 1112

The author describes observations on the effect of ultrasonic waves on red blood corpuscles using an ultrasonic generator with a frequency 18000 cycles per second and a power 11470 Watts per second. The test was made

with saline suspensions containing from 20,000 to 900,000 erythrocytes per cmm. The results were assessed by removing samples at regular intervals and counting the red cells in a haemocytometer, the number destroyed being expressed in percentage of the total number of erythrocytes present at the beginning of the experiment.

It was found that the speed with which the red cells were destroyed was inversely proportional to the concentration of the suspension and also depended on the power generated. Macroscopic haemolysis is produced when the concentration of red cells in the suspension is about 2,000-5,000 per cmm. It was impossible to follow the morphological changes in the erythrocytes, for they broke up suddenly, without any preliminary alterations. C. A. Hoare

SCHOENAERS, F. Contribution à l'étude de l'action des ultrasons sur les trypanosomes [Effect of Ultrasonic Waves on Trypanosomes] C. R. Soc. Biol. 1948, Aug., v. 142, Nos 15/16, 1082-4, 1 fig.

The author records observations on the effect of ultrasonic waves on trypanosomes (*T. equiperdum*, *T. evansi*, *T. brucei*, *T. gambiense*, and *T. rhodesiense*) suspended in saline, using a generator described in a previous paper [see above]. The response of the different species of trypanosomes was similar. The rate and degree of destruction of the flagellates depended upon the amount of energy emitted and upon the concentration of the trypanosomes in the suspension. For the same amount of energy the speed of destruction is inversely proportional to the concentration: thus a suspension of 14,000 trypanosomes per cmm. is lysed in 20 seconds, while 75 seconds are required to produce the same effect in a suspension of 48,000 trypanosomes. The different phases of disintegration of the flagellates can be followed under the microscope in Giemsa-stained films. However, the ultrasonic waves do not act upon all the trypanosomes to the same extent: for some individuals may remain morphologically intact, retaining their motility and virulence, longer than others. By inoculating mice with samples of the treated suspension taken at different intervals, infections were produced with a progressively prolonged duration until—after sufficient exposure to the ultrasonic waves—the mice survived. This phase indicates the destruction of all the trypanosomes in the suspension. C. A. Hoare

NYDEN, Shirley J. Changes in Ascorbic Acid Metabolism of the Rat during Infection with *Trypanosoma lippicum*. Proc. Soc. Exper. Biol. & Med. 1948, Nov., v. 69, No. 2, 206-10 [11 refs.]

Dehydroascorbic and total ascorbic acid were measured in the liver, spleen, adrenals, muscle, and plasma of rats infected with *T. lippicum* and the reduced ascorbic acid content of these tissues was calculated. The liver, spleen and adrenals showed significant decreases in reduced ascorbic acid content. The dehydroascorbic acid content of the muscle was increased slightly and both dehydroascorbic and reduced ascorbic acid of the plasma were increased two-fold.

TALLER, R. A. Indices de infección tripanosomica humana en el Uruguay. [Index of Infection by *Trypanosoma cruzi* in Uruguay] An. Facul. de Med. Montevideo 1948, v. 33, Nos 5, 6 & 7, 466-78, 4 figs. on 2 pls. Bibliography 1.

In the author's opinion the surest way of diagnosing *T. cruzi* infection is that of xenodiagnosis or, as he prefers to call it, xenohaemoculture, for it is cultivation of the blood of the subject in the intestine of an uninfected

Triatoma He describes his method of rearing *Triatoma infestans*, *T. marginata* and *Rhodnius prolixus* the first two obtained in Uruguay the last two from the Oswaldo Cruz Institute Rio de Janeiro. In the town of Rherra in 1946 among 284 tested by this method 20 (7.0 per cent.) were positive and in Tamboré and Valle-Edén in the Department of Tacuarembó there were respectively 139 and 60 tested and 1 (8.6 per cent.) and 3 (5 per cent.) positive. All those tested were under 14 years of age and chosen haphazard among those living in infested ranches. In a future paper the author proposes to give an account of the clinical condition and the electrocardiographic state of some of these subjects.

LEISHMANIASIS

ALGERIA. Cas de leishmaniose avec une érythémie réactionnelle secondaire (A Case of Leishmaniasis with Secondary Erythema.) I. *Soc. Méd. de Méd. Trop.* 1947 Dec. 31 v. 7 No. 4 419-27

An Algerian male aged 59 years who had maintained good health all his life but had two small accidents the last one during the previous year involving severe bruising in the left flank at the level of the 14th rib, presented himself complaining of a dull pain in the left flank, anæmia and emaciation.

On examination he was noted to have a cyanotic tinge of the lips of his face and limbs with varicosities on the latter and his tongue was scarlet. He had gross splenomegaly reaching down to the level of his umbilicus moderate liver enlargement, a little fluid in the left pleural cavity and a temperature of 38°C. The blood count showed a polycythæmia (7 million / cmm.) 18,000 leucocytes with neutrophils—84 per cent monocytes 7 per cent., and myelocytes— per cent. There were albumin and bile salt and pigment in the urine. A little fluid was withdrawn from the chest. Sternal puncture showed 31 per cent of erythroblasts of which 10 per cent were megakaryoblasts. Leucopelliculation of the serum occurred on the addition of formalin, and free leishmanias were found in the peripheral blood but not in the serum or spleen puncture material. A blood culture for *N. meningitidis* showed no old bodies but no flagellates. A diagnosis of kala-azar was made and a course of antimony was begun on August 14th. On August 14th the pain in the left flank had disappeared. A total of 3.5 grammes of *antimony tartar* was given. On September 19th the blood count still showed a polycythæmia of 7 millions but the leucocytes had fallen to 6,000. On October 1st, the count was 6 million red cells and 7,900 leucocytes and next day it was noted that his condition had improved considerably the spleen was reduced to a hand's breadth below the costal margin and the weight 63 kilograms. By November 15th, the condition had relapsed the spleen had enlarged and the weight was down to 60 kilograms. From November 18th the patient was given daily intramuscular injections of *glucan*. On November 20th, a few leishmanias were found in epithelial cells in a nasal smear. The patient improved rapidly and by December 15th the blood count was normal. After 18 injections his weight had recovered to 63.9 kilograms and the spleen was reduced to half its former size. A nasal smear was negative and on January 25th 1948 the man returned to his homeland.

The author considered that this was primarily a case of kala azar in which there was a stimulation instead of a depression of the marrow, causing a secondary polycythaemia

[Surprising features of this case were the failure to find leishmaniae in the spleen and bone marrow when free forms were found in the blood and nasal smears, and the absence of flagellates in the N N N culture] *L E Napier*

MORTON, T C & COOKE, J N C **Splenectomy in Kala-Azar** *Lancet* 1948, Dec 11, 920-23, 2 figs [12 refs]

"Splenectomy has come to be regarded as entirely contra-indicated in the treatment of kala-azar", but the authors report three cases which suggest that it may be the only method of cure in drug-resistant cases

They review the literature on splenectomy from MAKKAS [*Kala Azar Bulletin*, 1912, March, 94] to SWEENEY *et al* [this *Bulletin*, 1946, v 43, 114], in this last case, splenectomy was performed successfully, but as the result of an error of diagnosis. The present authors report a similar case—An airman recently returned from India had a large palpable mass in the left hypochondrium, anaemia and leucopenia, and albumin and pus in his urine. A sternal puncture showed no leishmaniae. His spleen, weighing 3,111 grammes, was removed. Leishmaniae were demonstrated in the smears and sections. Pentostam up to a total of 14.2 grammes was given and a complete cure was effected.

In several further quotations from the literature the authors refer to 4 instances of splenectomy in drug-resistant cases [TIMPANO, this *Bulletin*, 1931, v 28, 157; ABRAMI *et al* *ibid*, 1932, v 29, 499; MARTIN *et al* *ibid*, 1936, v 33, 30; BURCHENAL *et al* *ibid*, 1948, v 45, 319], and then report two fresh cases. The first of these was a patient of Professor Witts. He had had service in the Sudan and the Mediterranean littoral. He became ill four months after his return to Britain. He had pyrexia of 11 weeks' duration, moderate anaemia and leucopenia (2,600 per cmm), and a gradually enlarging spleen. All tests, including sternal puncture, were negative and he responded poorly to a course of neostibosan. After a second course of neostibosan a splenectomy was performed and a course of neostam was given. *Leishmania donovani* was found in the spleen. He became afebrile, gained in weight and his blood picture improved. He was eventually discharged cured. This patient showed a persistent lymphocytosis after splenectomy.

The other case was the authors' own, a 24-year-old corporal who developed kala azar in Calcutta and was given a course of treatment (urea-stibamine, 2.9 grammes) to which he responded well clinically. When he returned to England his spleen was still large. He was then given a course of pentostam forte (3.6 grammes). Sternal marrow still showed leishmaniae. After a further course of pentostam (3.6 grammes) sternal marrow was negative in smears and culture, but after a course of pentamidine isethionate (4.32 gm) the sternal puncture culture again became positive. Further courses of pentostam (3.6 gm and 3.6 gm) and pentamidine (2.6 gm and 2.0 gm) each caused a temporary clinical improvement but the man went steadily downhill. His sternal puncture showed no parasites but spleen puncture showed innumerable leishmaniae. His leucocyte count tended to fall after the commencement of each antimony course. This fall was confined mainly to the granulocytes. The spleen (2,736 grammes) was removed, after this the leucocyte count, which was below 2,000, rose to nearly 20,000 per cmm and there was a general all-round improvement which has been maintained for over 6 months. At the time of the splenectomy he was receiving a course of carbostibamide and he was subsequently given another course of pentamidine. The leucocyte count later dropped to the region of 10,000 with a lymphocyte percentage of 55 to 65.

The strain of *Leishmania donovani* isolated from this patient showed no antimony resistance, the authors therefore conclude that this resistance is a character of the patient. They discuss the possibility that early inadequate treatment may lead to antimony resistance. They consider that the leishmaniae were largely confined to the spleen where the blood stasis in the large vessels prevented the specific drugs reaching the parasites in adequate strength so that the spleen acted as a reservoir from whence parasites periodically reseeded other tissues.

They suggest that splenectomy should be considered in selected drug-resistant cases of kala-azar. [Another relapse has since occurred in the present case—a report on this will be published later.]

L. E. N. H.

OSWES, M. Cutaneous Leishmaniasis. A Case Report. *Chung Hwa Yü* [Shanghai] 1948 June v 68 No 8 727

A man of 48 who had lived in Mukden since 1941 complained of an itchy or but painless mass in the left hypochondrium and also of fever and weakness. He was very emaciated and anaemic and had an extensive splenomegaly. Leishman-Donovan bodies were found on sternal puncture.

Neostam treatment was begun and the next day itching papules were seen on the arms, especially on the extensor surface; each papule was surrounded by a pink halo. The papules increased in a few days to small nodules with central necrosis. Many Leishman-Donovan bodies were found in a serous or serous fluid from one of the nodules. The ulcers healed up in a few days without local treatment, as neostam therapy continued. It is added that the patient also had pustular scabies but there was no similarity between the two eruptions and they were treated separately.

The author comments that the patient had the ordinary type of kala-azar frequently seen in Mukden, which was confirmed by the finding of Leishman-Donovan bodies.

The cutaneous eruption on the other hand was unusual in that it appeared when the patient began his first specific treatment and it disappeared during the course of it, thus differing from dermal leishmanoid which usually appears a year or more after visceral manifestations have disappeared. The author states in fact that the skin condition more closely resembled a true cutaneous leishmaniasis.

LIU, Wei-T'ung Well-Felix Reaction in Typhus and Non-Typhus Fevers
Chinese Med J Shanghai 1948, June, v 66, No 6, 291-306 [45 refs]

The author, working at the Peiping Union Medical College Hospital, has made a careful study of the Weil-Felix reaction in 286 typhus patients and in 75 persons not suffering from typhus. Tests were carried out at intervals in these cases and single tests were made in more than 2,300 other cases of febrile diseases. The paper contains a documented summary of the findings of other observers of the reaction and a bibliography with 45 references to the literature.

The findings and conclusions of the author conform generally with those of most other workers on the subject.

In the series of 286 cases of typhus fever the reaction was persistently negative in 6.6 per cent, the maximum titre was 1-40 in 3.5 per cent, it was 1-80 in 8.1 per cent, and 1-160 in 10.1 per cent. Very high titres of 1-2,560 or over occurred in 25.2 per cent.

Among 141 patients tested during the first week positive reactions occurred in 37.6 per cent, during the second week a further 55.3 per cent became positive, and only 6.4 per cent were delayed to the third week.

Among 2,398 cases of fevers other than typhus 7.4 per cent reacted at titres ranging from 1-40 to 1-1,280. Dual infection was suspected in two cases. Among 75 cases of fevers other than typhus in which tests were carried out on several occasions there were 7 in which a falling-titre agglutination occurred, and 12 in which the titres reached 1-80 or 1-160, including two in which dual infection was suspected.

SMART, J Llee *British Museum (Natural History) Economic Ser No 2A*
2nd Edition 1948 31 pp, 3 figs [10 refs] Printed by Order of the
Trustees of the British Museum [9d] [Summary appears also in
Bulletin of Hygiene]

Since the first edition of this booklet [see *Bulletin of Hygiene*, 1943, v 18, 316] a very great advance in louse control has been achieved by the use of DDT. The author has introduced several new paragraphs and sections, in the appropriate places, to describe these new methods. But, at the same time, the more efficient of the older methods of louse control are retained, in case of the possibility of louse infestation in circumstances where DDT was not available.

HARRISON, J L A Key to the Rats of Malaya Reprinted from *Malayan Nature J* 1948, v 3, No 3, 130-41

Twenty species of rats belonging to the family Muridae, and two species of Rhizomyidae, are briefly described, a key is supplied for their recognition by external characters.

It is stated that Malaysia seems to have been the centre in which rats have originally been evolved, and from which they have spread to the rest of the world.

The paper has been written for the purpose of enlisting the help of amateur naturalists in collecting further information with regard to the rats of Malaya. [See AUDY, below]

John W D Megaw

POMALES LEBRÓN A Studies on Murine Typhus in Puerto Rico *Puerto Rico J Pub Health & Trop Med* 1948, Mar, v 23, No 3, 393-407, 1 fig
[Spanish version 408-21]

This is a summary of work done on murine typhus in Porto Rico, where the existence of the disease was first recognized in 1940, and where, since that time, about 700 cases have been reported from San Juan alone.

[The English version of the paper by an obvious mis-translation later than 700 cases were reported up to 1940.]

Many sera of patients have been examined by the late Col. Harry Platt, who found a striking lack of correlation between the titres of the Weill-Felix complement fixation reactions. For example one case with a Weill-Felix titre of 1-102,400 gave a fixation titre of 1-20 for murine typhus, and 1-16 for epidemic typhus. In one case the epidemic titre was 1-640 and the murine 1-320 though the train was definitely orchitic.

The titres of a number of complement-fixation tests carried out by Dr H. Bengtson are reported. In these the responses to murine antigen were mostly at twice to four times higher titres than those to epidemic typhus but in two cases the titres were the same with both antigens—1-640 and 1-1,024 respectively.

Among 443 rats trapped at San Juan between December 1944 and June 1945 54 per cent gave positive fixation reactions.

The urine and faeces of 12 experimentally infected white rats remained non-infective; the blood became infective in four to seven days and remained so for about three weeks. Infection persisted in the brains of the rats tested at periods ranging from 28 to 191 days after inoculation and in the kidneys, lungs, heart and spleen of two of the rats up to the 29th and 92nd day respectively.

Ten rats were infected by the intraperitoneal route with very large doses of murine rickettsiae; the animals died in three to six days; the urine was infective in four out of seven that were tested, and the faeces in three out of seven.

Great difficulty was experienced in infecting rats by feeding them with heavily infected material; this experience together with the shortness of the period for which infection persisted in the blood and organs of experimentally infected rats does not agree with the theory that feeding on the carcass of dead rats is an important and natural method of transmission among these animals nor with the view that infection with urine or faeces is one of the usual ways of transmission from rat to man.

GRIFF D & PINKERTON H. The Rickettsiostatic Action of Crystalline Penicillin Fractions in Embryonal Eggs. *Proc Soc Exp Biol & Med* 1948 June 1, 68 No. 2, 228-32. [16 refs.]

Penicillin V was found to be two to four times more effective than penicillin G in producing rickettsiostasis in typhus-infected embryonated eggs [murine strain]. Penicillin F di-hydro F and K were much less effective.

These results are regarded as throwing doubts on the validity of the trial of penicillin in human rickettsial infection.

[This point is perhaps of academic interest with regard to the treatment of human typhus now that chloramphenicol has been found so effective.]

SADUSE J F J., HOFFER Constance & FREEDMAN Mildred. Effect of Para Aminoobenzoic Acid upon the Clinical Course Rickettsiemia, and Development of Complement-fixing Antibodies of Murine Typhus in the Guinea Pig. *Amer J Trop Med* 1948 Sept. 28, No. 3, 673-82. [17 refs.]

In the more satisfactory of the two sets of experiment described seven guinea-pigs were treated with PABA for six days. Just after receiving the first dose they were inoculated with murine-typhus rickettsiae. At the same time seven control guinea-pigs were inoculated with similar amount of infective

material and all of them reacted in a typical manner with fever and scrotal reaction. Only one of the animals treated with PABA became febrile, this and one other had a moderate scrotal reaction.

Positive complement-fixation reactions occurred in both treated and control guineapigs, and rickettsial strains were recovered from all the treated animals that were tested between the 4th and 8th day after inoculation. The treated animals in which no clinical manifestations occurred were later found immune to murine infection.

WILEY, J S & FRITZ, R F Tentative Report on Expanded Murine Typhus Fever Control Operations in Southern States *Amer J Trop Med* 1948, July, v 28, No 4, 589-97, 6 figs

This paper consists of a succinct and well-illustrated description of the successful control measures organized in the Southern States of the U S A in 1945 against the rat flea. In the 122 counties in which murine typhus was most prevalent the incidence of the disease fell from 5,338 in 1944 to about 2,200 in 1947, and the decline appeared to be due to the systematic dusting with DDT of the holes and other haunts of rats. In the 460 counties in which dusting was not carried out the incidence remained almost constant, the percentage of rats infested by fleas and the *cheopis* index were very much higher than in the "dusted" counties.

The authors recognize that, although dusting gives speedier control than any other measures, lasting results cannot be obtained without systematic action against the rats.

It is stated that, according to present indications, transmission of infection from rat to man does not occur till 15-20 per cent of the rats show evidence of past or present infection. Among the instructive graphs which illustrate the paper there is one showing a remarkably close correlation between the seasonal incidence of the disease and the variations in the *cheopis* index.

Dusting was found to cause a reduction by 80 per cent in the average number of *X cheopis* found on each rat, and a similar reduction in *Nosopsyllus fasciatus*, the rat flea, *Leptopsylla segnis*, the mouse flea, and the two rat mites, *Echidnolaelaps echidninus* and *Laelaps bacoti*. Other ectoparasites were less effectively controlled, the flea, *Echidnophaga gallinacea* was reduced by 35 per cent, the mite *Liponyssus bacoti*, by 47 per cent, and the rat louse, *Polyplax spinulosa*, by 26 per cent.

As long as 180 days after dusting the reduction of *X cheopis* was still 70 per cent.

AUDY, J R Natural History and Scrub Typhus Reprinted from *Malayan Nature J* 1948, Sept, v 3, 114-29, 4 figs on 2 pls

This paper, like that of HARRISON [above], is addressed specially to amateur naturalists in Malaya, but professional workers also will find it a very readable and helpful introduction to the mites concerned in the transmission of scrub typhus.

The author expresses the hope that the American name "chigger" for larval trombiculids will be introduced into the English literature because of the unsuitability of the name "harvest mite". He adds, however, the warning that there must be no confusion with the chigoe or jigger flea of Africa, although both this flea and its popular name were originally derived from South America. [It is, perhaps, optimistic to hope that such confusion will not arise, the three names chigger, chigoe, and jigger are probably corruptions of the same Spanish word *chico*, meaning tiny, and their pronunciation is so similar that there is sure to be trouble.]

PHILIP C. B. & HOWLAND L. C. The Tropical Rat Mite *Lipomys* as an Experimental Vector of Rickettsialpox. *Am. J. Trop. Med. Hyg.* 1947, v. 23, No. 5 697-703 1 fig.

The authors have found that *Rickettsia* *slovakiae*, the causal agent of rickettsialpox, can be transmitted in the laboratory from mouse to mouse by the rat mite *Lipomys* *hacoti* which is much more widely distributed than the mite *Allothrombomys sanguineus* [the only known natural vector of the disease see this *Bulletin* 1947, v. 44, 411-417 697 and 690].

L. hacoti is known to feed readily on man in New York and elsewhere; it is also known to be an experimental vector and a natural host of murine typhus.

In the present investigation colonies of clean *L. hacoti* were allowed to feed on infected white mice and were later tested for infectivity by letting them feed on young and baby white mice. In the course of numerous experiments of this kind infection was transmitted to one group of four baby mice in each litter which excluded the possibility that transmission had occurred through the swallowing of the mites by the mice. Although this was the only experiment in which transmission by biting was successful, many of the mites which had fed on infected mice actually became infected, as was shown by injecting suspensions of their bodies into mice.

The observations of which details are given are not regarded as indicating that *L. hacoti* is an efficient vector.

Infection was demonstrated in the nymphal progeny of the infected mites and it was found to persist in a colony of mites for at least 34 days.

The author mentions that previous work has indicated a closer immunological relationship to Rocky Mountain spotted fever than to other rickettsial fevers, though the essentially negative Weil-Felix reaction is noteworthy. In a footnote it is stated that attempts to transmit infection by the tick *Dermacentor andersoni* have so far been unsuccessful. The negative Weil-Felix reaction and the transmission of infection through mites rather than ticks provides another instance which complicates reliance on individual characteristics in proposed classifications of the rickettsial fevers such as those earlier offered by Megaw and Felix.

[It should be pointed out that these earlier classifications based on the arthropod vectors and the type of the Weil-Felix response referred only to those rickettsial diseases for which the name typhus was regarded as suitable because of their clinical and pathological resemblance to historical typhus fever. Such rickettsial diseases as trench fever, Q fever, and rickettsialpox cannot variably be called typhus fevers or even typhus-like fevers.]

The antigenic and immunological properties of the typhus and other rickettsial fevers require further study and at present it is simply a question of choosing a provisional classification which will be most helpful to those engaged in the diagnosis, treatment, and control of these diseases. (See B. D. Megaw.)

PLETITSKY D. F. La tique *Dermacentor sibiricus* agent du typhus épidémique en Sibirie occidentale. The Tick *Dermacentor sibiricus* as a Vector of Epidemic Typhus in Western Siberia. *C. R. Acad. Sci. USSR* 1947, 55, No. 9, 877-881 fig. [Summary taken from *Rev. Inf. et Path. Exp.* No. 1948, Nov., v. 36, Pt. 11, 177.]

Apart from Murmelles fever which occurs in the Crimea and is transmitted by *Rhipicephalus sanguineus*, Laty the form of tick-borne spotted fever (atypical typhus) recorded in the Soviet Union has a similar symptom and etiology. The tick vectors are *Dermacentor sibiricus* Osten in south central Siberia (Krasnoyarsk) *Hemaphysalis conspersa* Koch in the Maritime Province of the Russian Far East and *D. sibiricus* Osten and *H. conspersa* in the region of

were the patients treated in the same hospital between 1900 and 1918 and a much larger proportion of these belonged to the higher age groups. The present approach to comparable conditions is found in the 11 patients of the present series who were less than 10 years old and the 19 control patients belonging to the same age group. Among the PARA treated cases the average duration of the fever was 5.8 days; among the controls it was 15.7 days; there was no death in either of these groups of children. It may be suggested that only the severest cases among children were admitted during the period 1900-33 seeing that the average yearly admission rate was just over one as compared with 11 in 1947. But even if the fullest allowance is made for disturbing factors the remarkably rapid improvement observed in the clinical condition strongly suggests that the drug was very effective.

Among the five patients in the present series who were over 20 years old the average duration of the fever was less than 8 days; whereas among the 36 controls of the same age group the average duration was about 17 days among the survivors of whom there were only 18.

A significant feature of the study was that treatment was started early, less than four days on the average after the onset. To adults a large initial dose of 8.0 gm. was given, and this was followed by doses of 3.0 gm. every two hours till the temperature fell to normal or longer if the clinical condition remained unsatisfactory. For children the dosage was generally two-thirds of the adult quantity.

In severe cases 3.0 to 6.0 gm. were given intravenously in the form of a 20 per cent. solution of sodium PARA at the same time as the first oral dose.

The blood level aimed at was 40 mgm. per 100 cc. but it appears that in one child aged eight years a level of 111 mgm. was reached on the fourth day of treatment after a total dosage of 117 gm. orally and 6.0 gm. intravenously. No harmful results were observed from high blood levels maintained for short periods of time.

[Comparative tests of PARA and chloromycetin will doubtless be made in fevers of the typhus group; the latter drug appears to be more active especially for patients admitted after the 6th day. (See this Bulletin 1948 v. 45 1076 1077 1949 v. 46 27 131.) J. H. D. M.]

FINCHAM M. C., GUY E. G., LISTER L. M., WOODWARD T. L. & SWARTZ J. E. The Treatment of Rocky Mountain Spotted Fever with Chloromycetin. *Ann Intern Med* 1948 Oct. 29 v. 4 656-67 125.

Chloromycetin was given with remarkably good results in 15 patients suffering from Rocky Mountain spotted fever at the University Hospital, Baltimore in May, June and July 1948.

The average duration of the fever after the first dose was 4 days, the longest period being 16 hours. Striking improvement in the general condition was always observed by the end of the second day and in most cases convalescence was established within three days.

Rickettsiae had been isolated from the blood of seven patients and in all of these cases samples taken two days after the first dose was given were no longer infective but the development of agglutinin and complement fixing antibodies seemed to progress in the usual way.

In a few cases there was vomiting after the first or second dose; this was suspected of being due to psychic factors and the bitter taste of the drug.

No other evidence of toxicity was found though regular examination of the blood and urine were made.

[The controls were not strictly comparable; there were 46 cases treated at the hospital between 1900 and 1948 and it seems possible that fewer mild

cases were being admitted during that period. Comparison with the effects of treatment by *para*-aminobenzoic acid as reported by WOODWARD *et al* (see above) may be more appropriate, in that series the average duration of the fever after the first dose was 3.2 days. But the evidence of the efficacy of chloromycetin is very convincing.]

The drug was given by the mouth, in most cases 0.5 gm was given every three hours till the rectal temperature had remained below 100°F for 24 hours. The first dose was given in three parts at intervals of one hour. The dose for children under 16 years of age was half the above.

The authors suggest the possibility of the occurrence of latent infection after an incomplete course of treatment.

[For previous reports of the effect of the drug in the treatment of epidemic typhus and scrub typhus see this *Bulletin*, 1948, v 45, 779, 1077, 1949, v 46, 27.]

John W D Megaw

COOKE, C. Rocky Mountain Spotted Fever treated with Aureomycin. *J Amer Med Ass* 1948, Nov 20, v 138, No 12, 885, 1 chart

Rocky Mountain spotted fever is not uncommon in the eastern part of Long Island, N Y and there are usually 10 to 15 cases annually in Suffolk county. The mortality varies throughout the country in some places and in some years from 15 per cent to as high as 37.5 per cent in the Bitter Root Valley.

The author records the case of a woman of 28 who was admitted to Huntington Hospital in July, 1948 with a three-day history indicating an acute exanthem. In the previous two weeks she had found two or three embedded ticks on her body, the last about six days before the illness began. There was no history of exposure to contaminated food or water or evidence of rat or louse infestation.

The clinical examination which is described suggested a diagnosis of Rocky Mountain spotted fever. Pending results of blood culture to exclude meningococcaemia, 900,000 units of penicillin in 3 doses at intervals of six hours were given and discontinued when the blood culture proved negative.

Some aureomycin was obtained and given orally from the day after admission (the fourth day of illness) in a dosage of 1 gm every six hours for 48 hours at the beginning of treatment, the rash was pronounced and violaceous and the temperature was spiking to 104°F. After 48 hours of treatment, it had returned to normal and the symptoms had abated dramatically. The dosage of aureomycin was reduced to 0.5 gm every 6 hours for the next 24 hours, making a total of 10 gm. There was no evidence of toxicity other than that of transitory (and probably unrelated) nausea and vomiting. Improvement continued, the rash had gone on the ninth day and the patient was discharged on the tenth. Blood, urine and stool examinations and cultures were negative, as were serological tests, except that on the fourth day (when other agglutination and complement-fixation tests were negative), the patient's serum agglutinated *Proteus OX19* at a titre of 1/40. On the tenth day, however, the reaction to the complement-fixation test was positive for Rocky Mountain spotted fever in a titre of 1/88. This was confirmed by Dr Cox at the Lederle Laboratories who reported a positive result at 1/64. The reaction to rickettsialpox complement-fixation (which has been found to be somewhat more sensitive in detection of "spotted fever" early in the disease) also became positive, in lower titre, by the tenth day.

The author observes that in a disease where a severe febrile course of 2 to 3 weeks might be expected, response to aureomycin was prompt and that this is further evidence of its efficacy against the rickettsiae of Rocky Mountain spotted fever.

H J O'D Burke-Gaffney

LACKMAN D & PARKER R. R. Comparison of the Immunogenic and Anaphylactogenic Properties of Rocky Mountain Spotted Fever Vaccines prepared from Infected Yolk Sacs and from Infected Tick Tissues. *Am J Pub Health* 1948, Oct. v 38 No. 10 1402-4

Rocky Mountain spotted fever vaccines prepared from infected yolk sacs and from tick tissues were about equally active in producing immunity in guinea pigs. The protein present in the tick tissue vaccines failed to produce anaphylaxis in guinea pigs whereas that present in yolk-sac vaccines produced anaphylaxis in 58 per cent of the guinea pigs tested

JELLINEK W. L., BELL E. J., HUENNER, R. J., PARKER R. R. & WELSH H. R. Q Fever Studies in Southern California. IV Occurrence of *Coxiella burnetii* in the Spinose Ear Tick, *Otobius megnini*. *Pub Health Rpt. Wash.* 1948 Vol. 17 v 63 No 46 1483-9 [1st refs.]

The authors have isolated 10 strains of Q-fever rickettsiae from batches of nymphal ticks belonging to the family of Argasidae. The ticks were *Otobius megnini* which were collected from the ears of cattle belonging to four dairies in which the organism had been isolated from raw milk. In one of the dairies cases of Q fever had occurred among persons employed in the dairy. (See this *Bulletin* 1943 v 45 509)

Altogether 246 lots of ticks were examined in the course of the investigation. Evidence of transmission of the disease by ticks in California had hitherto been lacking because ticks had never been found on cattle of the infected herds, but after attention had been called to the occurrence of *O. megnini* on cattle of similar herds a search was made with the interesting result that infection had been discovered for the first time in the U.S.A. among Argasid ticks.

It is stated that in addition to the two species of *Dermacentor* and one of *Amblyomma* already found naturally infected in the U.S.A. two other species of ticks have been found naturally infected in that country, but the data have not yet been published.

One lot of four infected ticks was found on a cow whose serum gave a positive complement fixation reaction at 1:128. Another lot of five was from a cow reacting at 1:8. The other lot of infected ticks consisting of 20-3 were from batches of cows, only some of which gave positive reaction.

The guinea pigs employed in isolating the strains gave typical febrile reactions, fixation responses at titres of 1:128 to 1:2048 and typical lesions of experimental Q fever were found, including numerous rickettsiae in areas of the exudate at the site of subcutaneous inoculation.

Although *O. megnini* is the first Argasid tick found naturally infected in the U.S.A. (this *Bulletin* 1943 v 40 805) has reported experimental infection in two other species, *Ornithodoros monticola* and *O. hermsi* and in the former of these transovarial infection has been reported. A *O. megnini* feed upon a single host this type of infection must occur if the ticks are ectoparasites of the livestock.

The authors appear to have accepted the view of PHILLIPS that the organism of Q fever belongs to a genus distinct from the true rickettsiae and has adopted the name *Coxiella burnetii* instead of the original name *R. burnetii* and the name *R. ad. parvum* formerly used in the U.S.A. (see this *Bulletin* 1948 45 474)

J. H. D. MERRILL

DE RODA-HUENNE, Enid C. Cross-immune Reactions between Panamanian Strains of Q Fever and Endemic Typhus. *Trans. J. Trop. Med.* 1947, Sept. v 28 No. 3 663-8.

Four of six guinea pigs which had been immunized against murine typhus were regarded as showing a partial degree of immunity when challenged with

an inoculation of a Panama strain of Q fever, the average duration of the incubation period and of the fever was appreciably shorter than in the four control animals. Two other guineapigs immunized in the same way were challenged with a yolk-sac suspension of the same strain of Q fever, they and the two controls were equally overwhelmed by the challenging strain.

In the reverse experiments, 12 guineapigs convalescent from experimentally produced Q fever were challenged with murine-typhus infection and showed no significant protection against the febrile reaction, but only two of them developed scrotal reactions whereas nine of the twelve control animals had reactions.

With complement-fixation tests no significant cross reactions were observed.

[Some workers may doubt whether such degrees of partial immunity as were observed in these experiments are due to specific rickettsial antibodies. Guinea-pigs convalescent from attacks of experimental rickettsial diseases are not strictly comparable with previously healthy control animals.]

John W D Megaw

OLIPHANT, J W & PARKER, R R Q Fever Three Cases of Laboratory Infection *Pub Health Rep Wash* 1948, Oct 15, v 63, No 42, 1364-70, 3 figs

Three cases of laboratory infection with Q fever are described, they occurred in August 1947, January 1948, and February 1948, respectively, at the Rocky Mountain Laboratory where work on the rickettsiae of the disease has been carried out more or less continuously since 1935.

Mention is made of three previous cases which occurred among employees of the laboratory in January 1941, April 1941, and March 1942. One of these persons had not been known to have been in contact with the block of buildings in which work on Q fever was being done.

One of the present patients was employed in a unit engaged in the production of Q fever yolk-sac vaccine, another was working in a unit in which animal inoculations with Q fever rickettsiae were carried out, the third was a frequent visitor to the office rooms of the Laboratory.

The mode of infection is not discussed.

John W D Megaw

RABIES

KOPROWSKI, H & COX, H R Occurrence of Rabies Virus in the Blood of Developing Chick Embryo *Proc Soc Exper Biol & Med* 1948, July-Aug, v 68, No 3, 612-15 [12 refs]

The authors, in the course of previous studies on rabies infection in the developing chick embryo (*J Bacteriology*, 1947, v 54, 74, abstract of a paper read at a meeting of the Society of American Bacteriologists), had obtained results, which indicated a distribution of rabies virus throughout the tissues of the embryo with no particular affinity to the central nervous system and which suggested a haematological spread of the virus and, therefore, presence of the virus in the blood of the embryo.

In connexion with the latter possibility, the authors carried out a further series of experiments, the results of which may be summarized as follows.

Rabies virus (FLURY strain) was inoculated by the yolk-sac route into 7-day-old chick embryos. By means of intra-cerebral injections into albino Swiss mice, 21 to 28 days old, the virus was recovered from the chick-embryo

LACKMAN D & PARKER, R. R. Comparison of the Immunogenic and Anaphylatogenic Properties of Rocky Mountain Spotted Fever Vaccines prepared from Infected Yolk Sacs and from Infected Tick Tissues. (See *J. Pub Health* 1948 Oct., v 38 No. 10 1407-4)

Rocky Mountain spotted fever vaccines prepared from infected yolk sacs and from tick tissue were about equally active in producing immunity in guinea pigs. The protein present in the tick tissue vaccines failed to produce anaphylaxis in guinea pigs whereas that present in yolk-sac vaccines produced anaphylaxis in 33 per cent of the guinea pig tested.

JELLISON W. L., BELL E. J., HUTCHINS R. J., PARKER R. R. & WALSH J. H. Q Fever Studies in Southern California. II. Occurrence of *Coxiella burnetii* in the Spinose Ear Tick, *Otiobius murrayi*. *Pub Health Rep. Wash.* 1948 Nov. 12, v 63 No. 46 1483-9. (1st ref.)

The authors have isolated 10 strains of Q-fever rickettsia from batches of nymphal ticks belonging to the family of Argasidae. The ticks were *O. murrayi* which were collected from the ears of cattle belonging to four dairies in which the organism had been isolated from raw milk. In one of the dairies cases of Q fever had occurred among persons employed in the dairy. (See this Bulletin 1943 v 43 509)

Altogether 46 lots of ticks were examined in the course of the investigation. Evidence of transmission of the disease by tick in California had hitherto been lacking because ticks had never been found on cattle of the infected herd, but after attention had been called to the occurrence of *O. murrayi* on cattle of similar herds a search was made with the interesting result that infection has been discovered for the first time in the U.S.A. among Argasid ticks.

It is stated that in addition to the two species of *Dermacentor* and one of *Haemaphysalis* already found naturally infected in the U.S.A. two other species of ticks have been found naturally infected in that country, but the data have not yet been published.

One lot of four infected ticks was found on a cow whose serum gave a positive complement-fixation reaction at 1:128. Another lot of five was from a cow reacting at 1:8. The other lots of infected ticks comprised of 20-25 were from batches of cows, only some of which gave a positive reaction.

The guinea pig employed in isolating the strains gave typical febrile reactions, fixation responses at titres of 1:128 to 1:2,048 and typical lesions of experimental Q fever were found including numerous rickettsiae in masses of the exudate at the site of subcutaneous inoculation.

Although *O. murrayi* is the first Argasid tick found naturally infected. Dyer (this Bulletin 1943 v 40 905) has reported experimental infection in other species *Ornithodoros montanus* and *O. hermsi* and in the form of trans-ovarial infection has been reported. A *O. murrayi* feed only on a single host this type of infection must occur if the tick is a vector of the disease.

The authors appear to have accepted the view of PARKER that the organism of Q fever belongs to a genus distinct from the true rickettsiae and have adopted the name *Coxiella burnetii* in stead of the original name *R. burnetii* and the name *R. diaforica* formerly used in the U.S.A. (See this Bulletin 1949, 49 441)

J. H. D. M. J.

DE ROPANICHE, ENID C. Cross-Immune Reactions between Panamanian Strains of Q Fever and Endemic Typhus. (See *J. Trop. Med.* 1949 Sept. v 28 No. 5 683-6)

Four of six guinea pigs which had been immunized against murine typhus were regarded as showing a partial degree of immunity when challenged with

an inoculation of a Panama strain of Q fever, the average duration of the incubation period and of the fever was appreciably shorter than in the four control animals. Two other guineapigs immunized in the same way were challenged with a yolk-sac suspension of the same strain of Q fever, they and the two controls were equally overwhelmed by the challenging strain.

In the reverse experiments, 12 guineapigs convalescent from experimentally produced Q fever were challenged with murine-typhus infection and showed no significant protection against the febrile reaction, but only two of them developed scrotal reactions whereas nine of the twelve control animals had reactions.

With complement-fixation tests no significant cross reactions were observed.

[Some workers may doubt whether such degrees of partial immunity as were observed in these experiments are due to specific rickettsial antibodies. Guineapigs convalescent from attacks of experimental rickettsial diseases are not strictly comparable with previously healthy control animals.]

OLIPHANT, J W & PARKER, R R Q Fever Three Cases of Laboratory Infection. *Pub Health Rep Wash* 1948, Oct 15, v 63, No 42, 1364-70, 3 figs

Three cases of laboratory infection with Q fever are described, they occurred in August 1947, January 1948, and February 1948, respectively, at the Rocky Mountain Laboratory where work on the rickettsiae of the disease has been carried out more or less continuously since 1935.

Mention is made of three previous cases which occurred among employees of the laboratory in January 1941, April 1941, and March 1942. One of these persons had not been known to have been in contact with the block of buildings in which work on Q fever was being done.

One of the present patients was employed in a unit engaged in the production of Q fever yolk-sac vaccine, another was working in a unit in which animal inoculations with Q fever rickettsiae were carried out, the third was a frequent visitor to the office rooms of the Laboratory.

The mode of infection is not discussed.

RABIES

KOPROWSKI, H & COX, H R Occurrence of Rabies Virus in the Blood of Developing Chick Embryo. *Proc Soc Exper Biol & Med* 1948, July-Aug, v 68, No 3, 612-15 [12 refs]

The authors, in the course of previous studies on rabies infection in the developing chick embryo (*J Bacteriology*, 1947, v 54, 74, abstract of a paper read at a meeting of the Society of American Bacteriologists), had obtained results, which indicated a distribution of rabies virus throughout the tissues of the embryo with no particular affinity to the central nervous system and which suggested a haematological spread of the virus and, therefore, presence of the virus in the blood of the embryo.

In connexion with the latter possibility, the authors carried out a further series of experiments, the results of which may be summarized as follows.

Rabies virus (FLURY strain) was inoculated by the yolk-sac route into 7-day-old chick embryos. By means of intra-cerebral injections into albino Swiss mice, 21 to 28 days old, the virus was recovered from the chick-embryo

LACOMAX D & PARKER R. R. Comparison of the Immunogenic and Anaphylactogenic Properties of Rocky Mountain Spotted Fever Vaccines prepared from Infected Yolk Sacs and from Infected Tick Tissues. *Am J Pub Health* 1948 Oct., 38 No. 10 1407-4

Rocky Mountain spotted fever vaccines prepared from infected yolk sacs and from tick tissues were about equally active in producing immunity in guinea pigs. The protein present in the tick tissue vaccines failed to produce anaphylaxis in guinea pigs whereas that present in yolk-sac vaccines produced anaphylaxis in 59 per cent of the guinea pig tested.

JELLINEK W. L., BELL E. J., HUEBNER R. J., PARKER, R. R. & WILSON H. H. Q Fever Studies in Southern California. IV Occurrence of *C. stellata* in the Spinose Ear Tick, *O. virescens*. *Pub Health Rep Wash* 1949 Nov 19, 63 No. 46, 1483-9 (12 refs.)

The authors have isolated 10 strains of Q-fever rickettsiae from batches of nymphal ticks belonging to the family of Argasidae. The ticks were *O. virescens* which were collected from the ears of cattle belonging to four dairies in which the organism had been isolated from raw milk. In one of the dairies cases of Q fever had occurred among persons employed in the dairy. (See this Bulletin 1948, 45 509)

Altogether 246 lots of ticks were examined in the course of the investigation.

Evidence of transmission of the disease by tick in California had hitherto been lacking because ticks had never been found on cattle of the infected herds, but after attention had been called to the occurrence of *O. virescens* on cattle of similar herds a search was made with the interesting result that infection has been discovered for the first time in the U.S.A. among Argasid ticks.

It is stated that in addition to the two species of *Dermacentor* and one of *Amblyomma* already found naturally infected in the U.S.A. two other species of ticks have been found naturally infected in that country, but the data have not yet been published.

One lot of four infected ticks was found on a cow whose serum gave a positive complement fixation reaction at 1:128, another lot of five was from a cow reacting at 1:8. The other lots of infected tick, consisting 120-25 were from batches of cows only some of which gave positive reaction.

The guinea pig employed in isolating the strain gave typical wheal reactions, fixation responses at titres of 1:128 to 1:648 and typical lesions of experimental Q fever were found, including numerous rickettsiae in smears of the exudate at the site of subcutaneous inoculation.

Although *O. virescens* is the first Argasid tick found naturally infected. Davis (this Bulletin 1943, 40 903) has reported experimental infection in the other species *Ornithodoros monstrosus* and *O. hermsi* and in the former of these transovarial infection has been reported. A *O. virescens* fed only on a single host this type of infection must occur if the tick is a vector of the disease.

[The authors appear to have accepted the view of Purcell that the organism of Q fever belongs to a genus distinct from the true rickettsiae and have adopted the name *Coxiella burnetii* in stead of the original name *R. burnetii* and the name *R. disporica* formerly used in the U.S.A. (See this Bulletin 1948, 45 471)]

DE KROSTCHKE, Erik C. Cross-immune Reactions between Panamanian Strains of Q Fever and Endemic Typhus. *Am J Trop Med* 1948, Sept., 28 No. 5 693-4.

Four of six guinea pigs which had been immunized against murine typhus were regarded as showing a partial degree of immunity when challenged with

an inoculation of a Panama strain of Q fever, the average duration of the incubation period and of the fever was appreciably shorter than in the four control animals. Two other guineapigs immunized in the same way were challenged with a yolk-sac suspension of the same strain of Q fever, they and the two controls were equally overwhelmed by the challenging strain.

In the reverse experiments, 12 guineapigs convalescent from experimentally produced Q fever were challenged with murine-typhus infection and showed no significant protection against the febrile reaction, but only two of them developed scrotal reactions whereas nine of the twelve control animals had reactions.

With complement-fixation tests no significant cross reactions were observed.

[Some workers may doubt whether such degrees of partial immunity as were observed in these experiments are due to specific rickettsial antibodies. Guineapigs convalescent from attacks of experimental rickettsial diseases are not strictly comparable with previously healthy control animals.]

RABIES

KOPROWSKI, H & COV, H R Occurrence of Rabies Virus in the Blood of Developing Chick Embryo *Proc Soc Exper Biol & Med* 1948, July-Aug, v 68, No 3, 612-15 [12 refs]

The authors, in the course of previous studies on rabies infection in the developing chick embryo (*J Bacteriology*, 1947, v 54, 74, abstract of a paper read at a meeting of the Society of American Bacteriologists), had obtained results which indicated a distribution of rabies virus throughout the tissues of the embryo with no particular affinity to the central nervous system and which suggested a haematological spread of the virus and, therefore, presence of the virus in the blood of the embryo.

In connexion with the latter possibility, the authors carried out a further series of experiments the results of which may be summarized as follows.

Rabies virus (FLURY strain) was inoculated by the yolk-sac route into 7-day-old chick embryos. By means of intra-cerebral injections into albino Swiss mice, 21 to 28 days old, the virus was recovered from the chick-embryo

blood from the 3rd to the 15th post inoculation day. Such finding was practically constant irrespective of the use for mouse inoculation of chick-embryo red blood cell in saline solution or of chick-embryo plasma undiluted or in serial tenfold dilutions with 10 per cent. rabbit serum-saline.

These results do not of course help to solve the still highly controversial question whether rabies virus is present in the blood of infected mammals.

G. Stuart

PAWAX, J. L. Fruit Eating Bats and Paralytic Rabies in Trinidad. *J. Trop. Med. & Parasit.* 1948 Sept. v. 4, No. 2 173-7

For the past 16 years it has been generally recognized that the paralytic rabies of man and animal in Trinidad is ordinarily spread by the bite of the blood-sucking vampire bat *Desmodus rotundus* *synonymus* Wagner family *Desmodontidae*.

Two facts suggested however the possibility of vicarious rabies transmission to mammals by the bite of fruit-eating *Phyllostomidae* bat—normally non-blood feeders, viz (1) in Brazil during 1921 it had proved possible to produce paralytic rabies in rabbit and guinea pigs by the intramuscular injection of the brain of a "leaf nose" bat, *Phyllostomus* *sp. perillatum* Bornmeister and (2) in Trinidad a total of five fruit-eating bats, *Artibeus planicostatus* Latr—the commonest species found there—had been shown to have Negri bodies in their brains.

To determine definitely whether fruit-eating bats do at times bite mammals and so produce rabies was the object of the experiments described by the author in the present article.

Results showed that—as with the blood-sucking vampire bat—fruit-eating *Artibeus* bats may prove refractory to infection with rabies virus—but though they may not manifest any evidence of disease their saliva may carry infection. Fruit-eating bat when infected with rabies may bite mammals—not necessarily with the object of obtaining blood for food, but on account of a change in habit through being rabid. Mammals so bitten may develop rabies.

C. Stuart

JOHNSON, H. V. Dengue: Vampire Bat Rabies in Mexico. *Amer. J. Hyg.* 1948, Mar. v. 47 No. 2 169-94 18 of 1

Dengue (*el troyal* in some localities) is the ordinary Spanish name for a highly fatal paralytic disease of livestock, especially cattle, which for nearly half a century has been prevalent in the Pacific coast States of Mexico and which in recent years has spread further and further inland as well as to the southwest.

In 1932 a virus which was considered to be the specific aetiological agent of dengue had been isolated from affected cattle but although its symptomatology and pathology the experimental disease produced by this virus closely resembled rabies, the antigenic relationship of the viruses of the two diseases had not been determined.

Moreover on epidemiological grounds doubts had been cast on probable relationship from the fact that dengue was often epizootic in areas where canine rabies was unknown and that despite the noted similarity of dengue to paralytic rabies of vampire bat origin, vampire bat had not been shown to be in areas where dengue was abundant.

In 1943 from a specimen of brain tissue obtained from a cow exhibiting the characteristic paralytic disease was recovered a virus which later proved to be antigenically related to known strains of rabies virus.

Following on this finding the author was requested in 1944 by the Natural Sciences Division of the Rockefeller Foundation to undertake an epizootic

by a total of 24 gm. sulphadiazine or sulphathiazole for eight days. Antisera serum was also given—100 cc. on the 4th day and 25 cc. on each of the two following days.

By the 9th day the temperature fell to normal after a very severe illness. On the 11th day it rose again though plague bacilli could no longer be found in the sputum. Penicillin was then given for five days—700,000 units daily—and a further course of sulphonamide drugs totalling 30 gm. was given. From the 14th day the temperature remained normal and the patient made a good recovery. The first patient had received inoculation of live avirulent plague vaccine on several occasions the last being 10 days before his illness. The second patient had not been vaccinated.

HARRISON J. L. & WOODVILLE H. C. An Attempt to control House Rats in Rangoon. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1948 Nov., v. 4, N. 3 247-53, 1 fig.

The chief impression conveyed by this paper is that rat destruction by poisoning with barium carbonate is unlikely to make more than a partial and temporary impression on the rat population. In a large area in which preliminary baiting in accordance with accepted practice preceded the distribution of the poison it was found that the number of rats trapped nightly was reduced by about 60 per cent. The author concludes that barium carbonate is a low efficiency poison though in the summary he describes the results as satisfactory.

Figures quoted in the paper to show the results of previous efforts to control rats in Rangoon by trapping are interesting. In 1931 and the following four years the numbers of rats trapped were respectively 734,000, 69,000, 731,000, 718,000 and 569,000. [These figures suggest that trapping as carried out may almost be regarded as having a favourable influence on the rat population—from the point of view of the rats—by helping to maintain a satisfactory balance between the rat population and their food supply.]

In the present attempt at rat control gassing with Cyman gas gave poor results and so did trapping during the period May to November 1945.

The rodents found in Rangoon were *Bandicota bengalensis* (31 per cent.), *Rattus exulans* (45 per cent.), *A. stultus* (8 per cent.), *A. norvegicus* (6 per cent.), *Mus musculus* (5 per cent.) and the shrew *S. new-cornutus* (4 per cent.).

Plague infection was found in 9 of 41 *R. rattus* and in 1 of 75 *B. bengalensis*. The fleas found were *Xenopsylla asiatica* and *X. cheopis*.

On *R. rattus* which was regarded as the chief reservoir of infection the average number of *X. cheopis* was 0.30 and of *X. asiatica* 0.23.

WILCOX, A. & PEARCE, J. Indices of ecto-parasitism and the control of ectoparasites in Rats with DDT. *Riv. Chilena de Hig. y Med. Preventiva* 1948, June 16 N. 13 31-35 3 figs. 51 refs.

POLLITZER R. Plague and Plague Control in China. *Chin. Med. J.* Shanghai 1948 June 64, N. 6 324-33.

The author is an Epidemiologist of the World Health Organization in China Mission. He has presented a clear and succinct description of the plague situation in China during 1946 and 1947. The Province of Fukien was most severely affected having 6,141 reported cases in 1946 and 1,541 in 1947. The Provinces of Yunnan, Kwantung (Chekiang) and Kiangsu were less affected the number of cases ranging from 173 to 823.

The recent importation of the disease from Burma is regarded as a repetition of the invasion of more than 100 years ago, of which the final culmination was the historic outbreak at Canton and Hong Kong in 1894. The epidemiology of the disease in China appears to have been very similar to that observed in India. Points of interest are the frequent occurrence of pestis minor and the absence of septicaemic cases in Yunnan, and the occasional occurrence of limited outbreaks of primarily pneumonic plague in areas free from the disease. These outbreaks were always due to the arrival of a traveller from infected areas. Sulphadiazine is regarded as the best of the sulphonamide drugs. Reports of the cure of 50 per cent of cases of primary pneumonic plague at Mukden are not regarded as being based on satisfactory evidence.

Inoculation with formol-killed vaccine is regarded as definitely useful though it is not yet popular in China where even the medical men are said to be haunted by the quite unwarrantable fear of the negative phase.

Some observations are mentioned which suggest that persons exposed to risk of infection by pneumonic plague may be protected by prophylactic treatment with 3.0 gm sulphathiazole daily for three days.

CHOLERA

ZAKI, A & RAGAB, M M. Circulatory Dynamics in Cholera. Their Mechanism and Prognostic Significance. *J Roy Egyptian Med Ass* 1948, Oct, v 31, No 10, 770-85.

The circulatory changes in cholera were studied in relation to the degree of dehydration occurring, with consequent haemo-concentration and oligæmia. It was found that venous pressure was lowered in all cases and that the degree of lowering was proportionate to the severity of the case. Additional factors contributing to the fall in venous pressure were the increased viscosity of the blood, compensating vasoconstriction and loss of muscle tone. Arterial pressure is also lowered but is related to clinical severity to a lesser degree, the higher the diastolic pressure the better the prognosis. The circulation time was found to be only slightly prolonged and of no value in prognosis. Pulse rate is not a dependable sign. The circulatory failure in cholera is considered to be peripheral in origin.

J Taylor

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

STEWART, G T. The Role of Bacteria in Intestinal Amoebiasis in Man. *Ann Trop Med & Parasit* 1948, Sept, v 42, No 2, 198-206 [31 refs]

The bacterial flora of the intestines of 101 men suffering from amoebiasis was compared with that of 120 patients with no intestinal disorder. In early dysenteric cases there was a marked increase in the frequency of *Bact aerogenes*, and in late relapsing cases with chronic lesions in various stages of activity a significant increase of non-lactose-fermenting bacteria mainly identified as paracolon bacilli. The prevalence of *Strep faecalis* in both groups was thought to be a result of intestinal hurry [this *Bulletin*, 1948, v 45 788]. None of the recognized pathogens was isolated. Agglutinins to the predominant organisms were not found in the sera of the patients. It is considered that the increased

incidence of *Bact. aerogenes* is associated with the acid reaction of the stool and that the paracolonic bacilli and *Bact. coli* are potential pathogens introducing an added element of bacterial infection in a bowel which is the site of amoebic colitis. These findings may be related to the occurrence of "post-dysenteric colitis" and to the observation that cases of amoebic dysentery sometimes benefit from treatment with antibacterial agents.

J. C. Crumckhorn

SAMUEL, E. The Radiological Diagnosis of Chronic Amoebic Colitis. *Brit. J. Radiol.* 1943 Dec. v 21 No. 252, 425-31 10 figs.

This paper discusses the indications for and the place of radiology in the diagnosis of chronic amoebic colitis and also discusses the methods used. Most of the material and radiographs illustrating it are the same as those presented in the paper in which the present author collaborated with BREXER and SHEDDEN (this Bulletin 1940 v 48 148).

H. J. O. D. Burke-Gaffney

PARNELL, R. W. Diiodoquin compared with E.B.I. and Chinolone in the Early Treatment of Amoebic Dysentery in Burma. *J. Trop. Med. & Hyg.* 1943 Oct. v 51 No 10 200-202.

For this report only those cases have been selected in which a follow-up consisting of clinical examination, sigmoidoscopy and microscopic examination of three specimens of stool was completed after the courses of treatment described. The diagnosis was based in each case on finding typical motile *E. histolytica*.

Course I consisted of emetine E.B.I. and chunoion retention enemas (34 patients). 1 patients tested for cure one month after leaving hospital showed 14 apparently cured (=66 per cent). 13 patients tested one and again at two months showed 10 apparently cured (=77 per cent).

Course II consisted of emetine and diiodoquin (34 patients). 23 tested for cure one month after leaving hospital showed 18 apparently cured (=79 per cent). 11 tested at one and again at two months showed 7 apparently cured (=64 per cent).

The details of the courses are as follow —

Course I

Emetine 1 grain daily on days 1 to 8 and sulphaguanidine (a total of 100 gm. during days 1 to 3).

E.B.I. 4 grains daily on days 7 to 12 and chunoion retention enema (1 per cent.) on days 10 to 16.

Rest on days 17 to 19.

E.B.I. 3 grains daily on days 20 to 25.

Course II

Emetine 1 gram daily on days 1 to 6 and sulphaguanidine (a total of 100 gm. during days 1 to 3).

Diiodoquin 9.6 grains (3 tablets) 12 or 16 times daily on days 7 to 18.

In Group I nine had recent or associated bacillary colitis 6 of them had received sulphaguanidine for acute diarrhoea and 6 more had a history of bacillary dysentery.

In Group II (diiodoquin, 34 cases) 7 had a recent or a associated acute bacillary colitis on admission, 11 had received sulphaguanidine for acute diarrhoea 4 others had a history of bacillary dysentery.

In both groups only 37 per cent had no previous history recorded for acute diarrhoea in India or Burma.

It is concluded that in two groups treated early for amoebic dysentery in Burma no difference in effectiveness of treatment was noted between them

A relapse rate of more than 20 per cent was found within two months of treatment, by means of the standards of follow-up described

[It is not stated in what form the E B I was administered it has been shown that it is not absorbed in tablet form This appears to be the real gist of the matter] *P Manson-Bahr*

[The author, in a personal communication, has confirmed that the dosage schedules as given above are correct in the form in which they were set out in the original paper, there was some ambiguity —Ed]

ARMSTRONG, T G, POOLER, N R & ELSDON-DEW, R *Chlorobexol Clinical Trial of a New Treatment for Amoebiasis South African Med J* 1948, Nov 13, v 22, No 21, 691-2

The Amoebiasis Research Committee of the Natal Coastal Branch of the South African Medical Association investigated the claim, advertised to the medical profession, that Chlorobexol was a curative agent in amoebiasis

The active ingredients of this preparation are stated to be chlorophenoxy acid tetrachlor-para-benzoquinone, 2 per cent, hydrocarbon derivatives, 5 per cent, uranium chloride, 1 in 1,000,000

The preparation was used in 29 African patients, all of whom showed ulceration of the bowel and in whom vegetative forms of *E histolytica* were found in stools or scrapings Results were assessed in 7, 14 and 21 days in a number of patients treatment with emetine and diodoquin had to be given before the end of the test period, owing to serious deterioration in their general health The tests with chlorobexol were compared with a series of 50 cases treated with emetine (1 grain daily for 10 days) or diodoquin (10 tablets daily for 20 days)

The criteria in all cases were

(1) Ulcers covered with epithelium, no amoebae in scrapings and stools 'success'

(2) Open ulcers, no demonstrable amoebae probable failures

(3) Open ulcers and demonstrable amoebae absolute failures

After 14 days there was only one success out of the 29 patients, and after 21 days, there were only 2 successes in the 19 patients then remaining In the case of those controls treated with emetine, there were 25 successes out of 50 after 21 days and with diodoquin there were 29 out of 50

It is noted that among the 17 out of 19 patients who showed visible ulcers in the colon at the 21st day of chlorobexol treatment, none showed amoebae in the stools, but no less than 10 showed active amoebae in scrapings from ulcers, a reminder that negative stools are not a reliable criterion of the absence of amoebic infection It is added that in this series of investigations, in 57 different tests amoebae were found in the scrapings, but not in stools, on 45 occasions on 10 occasions they were found in both stools and scrapings and in two in stools, but not in scrapings

The Committee concludes, as a result of this investigation, that chlorobexol is not an effective amoebicidal agent and that the results of treatment with it are markedly inferior to those obtained with either emetine or diodoquin separately

H J O'D Burke-Gaffney

SCHNEIDER, J & MONTÉZIN, G *Amibiase expérimentale et amibiase spontanée du rat [Experimental and Spontaneous Amoebiasis in the Rat]* *Bull Soc Path Exot* 1948, v 41, Nos 7/8, 521-5

The authors, recognizing the limitations of the *in vitro* methods of testing amoebicidal drugs, have sought a good experimental host They believe the

kitten, although unresponsive to emetine to be the most suitable for difficulties, chiefly of supply prevented large-scale use of this animal. They therefore followed the experimental procedure of JOYNS (this *Bulletin* 1947 v 44 713) who used young rat weighing 20 to 33 gm for the evaluation of amoebicidal drugs after intracaeal inoculation of *E. histolytica* from cancer material. Like the original and other authors they found that the resulting infections were very variable as a result of this procedure. The amoebae present at autopsy could not be cultured in the usual media employed (a common experience with *E. muris*) cysts were rare and vegetative forms were seldom present in the rat faeces. These facts led them to doubt the nature of the infection and to suggest that the amoebae present were *E. muris* naturally infect the rat. A systematic survey of rats of different ages for the presence of natural infections with *E. muris* was carried out and the authors found that the distribution corresponded as regard age with that of amoebae in rats experimentally infected by the above procedure (older age groups are refractory). They quote inaccurately the results of HILTON & JOYNS (11 *Bulletin* 1948 v 45 430) who carried out a similar survey in a number of laboratory rodents because of the widespread occurrence of natural amoebic infections in rats used for chemotherapeutic test and adduce the evidence of these authors in further support of their own observations. It is not stated in the paper whether staining methods were used to determine the nature of the amoebae present in the rat gut. The authors' evidence that they were indeed *E. muris* is not convincing. While JOYNS in the paper quoted, made no mention of a natural amoebic infection in rat he did distinguish by staining methods the presence of *E. histolytica* in gut tissues. Vegetative forms and occasionally cysts, of this organism were sometimes present in rat faeces in the early stages of infection. The infection could not, however be regularly detected by examination or culture of the rat faeces. In a subsequent paper STEWART and JOYNS (this *Bulletin* 1948 45 1001) stated that one or more species of amoebae were sometimes present in the rat caecum and that there was no evidence that the experimental infections coincided with a natural infection. They were able to culture the amoebae present.

J. D. Fulton

LAMY, L. Le problème de la culture pure des amibes parasites. *Paris Culture of Parasitic Amoebae. C.R. Soc. Biol.* 1948 M v 147 Nos 9 10 633-4

Hitherto all attempts to grow the human intestinal amoeba, especially *Entamoeba histolytica* in pure culture, & in the absence of accompanying bacteria, have failed. The author has made an indirect approach to this question working with *E. muris* the pathogenic representative which can be cultivated at 25°C and is generally more amenable to experimental manipulation. It was hoped that results obtained with this amoeba would help to solve the problems of growing pure cultures of *E. histolytica*.

With the aid of de Fontbrune's micromanipulator a culture of *E. muris* associated with a single raphidococcus in media consisting of 10% of inspissated horse serum covered with a mixture of Ringer's solution and horse serum (6:1) with the addition of rice starch, small pieces of liver and a small amount of ground chick embryo. The sterility of the medium was controlled by broth cultures. The raphidococcus was eliminated from the pure mixed culture with *E. muris* by adding penicillin to 1000 units per cc. Up to the present the author has succeeded in obtaining several subcultures of the amoebae which were bacteriologically pure.

C. A. Hewitt

BARKSDALE, W L & ROUTH, C F *Isospora hominis* Infections among American Personnel in the Southwest Pacific *Amer J Trop Med* 1948, Sept, v 28, No 5, 639-44 [15 refs]

In the course of routine stool examinations in the South-West Pacific war area, the authors discovered 50 cases of infection with *Isospora hominis* among Americans, of whom 5 were from New Guinea, 5 from Leyte, 39 from Luzon and one from Japan. The Luzon cases represented 1.65 per cent of the persons examined (2,000 troops), including 16 found among 270 individuals belonging to one regiment. *Coccidia* were not detected in 750 Filipinos examined or in over 17,000 Japanese on Honshu.

The course of coccidiosis was followed in 15 patients kept under observation for 24 days. The symptoms ranged from slight intestinal disturbance to seizures with cramping, nausea and diarrhoea. The blood picture was normal, except for an eosinophilia of about 9.5 per cent. The oöcysts of *Isospora* were discharged in the stools cyclically, at irregular periods which lasted several days. When kept at 85-90°F the oöcysts underwent sporogony and matured in 48 hours.

No attempt was made to treat the disease, which is self-limited, but it was found that drugs used for concomitant disorders (tetrachlorethylene, emetine, carbarsone, chiniofon, diodoquin and atebirin [mepacrine]) had no action upon the coccidia, which continued to produce oöcysts. C A Hoare

MATSUBAYASHI, H & NOZAWA, T Experimental Infection of *Isospora hominis* in Man *Amer J Trop Med* 1948, Sept, v 28, No 5, 633-7, 2 figs

Human infections with *Isospora hominis* have been reported from Japan on six occasions since 1939. In two cases the infection was acquired in China, while the remaining four were of local origin. They were characterized by diarrhoea and various abdominal symptoms, without a rise of temperature. In order to observe the course of the disease, experimental infections of two volunteers were carried out, with oöcysts obtained from two different cases. The oöcysts were first washed by centrifugation and kept for more than 72 hours at 28°C, until sporogony was completed.

In the first experiment, a volunteer (one of the authors) ingested about 3,000 oöcysts. Eight days later symptoms of diarrhoea developed and there was a rise of temperature, the febrile condition lasting ten days, with temperatures above 39°C. On the following day the diarrhoea subsided but later the symptoms returned and were especially pronounced on the 17th day of the infection, after which they disappeared completely. Starting from the 9th day of the infection oöcysts of *I. hominis* were discharged regularly for 32 days.

Thirty-three days after the cessation of oöcyst-production in this person, he and another volunteer swallowed about 2,500 oöcysts each. In the first volunteer no infection resulted, probably owing to immunity acquired in the course of the original infection. In the second volunteer the course of the disease was similar to that described above, but the symptoms were more severe and oöcysts were discharged in the stools for six days longer. In both cases the symptoms disappeared without treatment after termination of oöcyst production. C A Hoare

COCKBURN, T A *Balantidium* Infection associated with Diarrhoea in Primates *Trans Roy Soc Trop Med & Hyg* 1948, Nov, v 42, No 3, 291-3

[A most interesting account] In June, 1947, at the London Zoological Society's Gardens a *Macaca nemestrina* (pigtail monkey) suffered from

kitten, although unresponsive to emetine to be the most suitable for difficulties chiefly of supply prevented large-scale use of this animal. They therefore followed the experimental procedure of JONES (this Bulletin 191 v 44 313) who used young rats weighing 20 to 33 gm. for the evaluation of amoebicidal drugs after intracæcal inoculation of *E. histolytica* from culture material. Like the original and other authors they found that the resulting infections were very variable as a result of this procedure. The amoebæ present at autopsy could not be cultured in the usual media employed (a common experience with *E. muris*) cysts were rare and vegetative forms were seldom present in the rat faeces. These facts led them to doubt the nature of the infection and to suggest that the amoebæ present were *E. muris* which naturally infect the rat. A systematic survey of rats of different ages for presence of natural infections with *E. muris* was carried out and the authors found that the distribution corresponded, as regards age, with that of amoebæ in rat experimentally infected by the above procedure (older age groups are refractory). They quote inaccurately the result of FULTON & JOYNER (this Bulletin 1918 v 45 430) who carried out a similar survey in a number of laboratory rodents because of the widespread occurrence of natural amoebæ infections in rats used for chemotherapeutic test and adduce the evidence of these authors in further support of their own observations. It is not stated in the paper whether staining methods were used to determine the nature of the amoebæ present in the rat gut. The authors' evidence that they were indeed *E. muris* is not convincing. While JONES in the paper quoted, makes no mention of a natural amoebic infection in rat, he did distinguish by staining methods the presence of *E. histolytica* in gut tissues. Vegetative forms and occasionally cysts of this organism were sometimes present in rat faeces in the early stages of infection. The infection could not however be regularly detected by examination or culture of the rat faeces. In a subsequent paper STEWART and JONES (this Bulletin 1948 v 45 1001) stated that one or more species of amoebæ were sometimes present in the rat caecum and that there was no evidence that the experimental infection coincided with a natural infection. They were able to culture the amoebæ present.

LAURE, L. Le problème de la culture pure des amibes parasites. *Pure Culture of Parasitic Amoebæ.* C.A. Soc. Biol. 1948 May v 147 No. 9 10 633-4

Hitherto all attempts to grow the human intestinal amoebæ (especially *Entamoeba histolytica*) in pure culture, in the absence of accompanying bacteria, have failed. The author has made an indirect approach to this question working with *E. mædis*, the pathogenic reptilian parasite which can be cultivated at 35°C and is generally more amenable to experimental manipulations. It was hoped that results obtained with this amoeba might help to solve the problem of growing pure cultures of *E. histolytica*.

With the aid of de Fonbrune's micromanipulator a culture was obtained of *E. mædis* associated with a single staphylococcus in media consisting of a slope of mepesinated horse serum covered with a mixture of Ringer's solution and horse serum (1:1) with the addition of one starch granule per 4 gms. liver and a small amount of ground chick embryo. The survival of the amoebæ was controlled by broth cultures. The staphylococcus eliminated from the pure mixed culture with *E. mædis* by adding penicillin or chloroform (1:1000 units per cc.) up to the present the author has succeeded in obtaining serial subcultures of the amoebæ which are bacteriologically sterile.

BARKSDALE, W L & ROUTH, C F *Isospora hominis* Infections among American Personnel in the Southwest Pacific *Amer J Trop Med* 1948, Sept, v 28, No 5, 639-44 [15 refs]

In the course of routine stool examinations in the South-West Pacific war area, the authors discovered 50 cases of infection with *Isospora hominis* among Americans, of whom 5 were from New Guinea, 5 from Leyte, 39 from Luzon and one from Japan. The Luzon cases represented 1.65 per cent of the persons examined (2,000 troops), including 16 found among 270 individuals belonging to one regiment. Coccidia were not detected in 750 Filipinos examined or in over 17,000 Japanese on Honshu.

The course of coccidiosis was followed in 15 patients kept under observation for 24 days. The symptoms ranged from slight intestinal disturbance to seizures with cramping, nausea and diarrhoea. The blood picture was normal, except for an eosinophilia of about 9.5 per cent. The oöcysts of *Isospora* were discharged in the stools cyclically, at irregular periods which lasted several days. When kept at 85-90°F the oöcysts underwent sporogony and matured in 48 hours.

No attempt was made to treat the disease, which is self-limited, but it was found that drugs used for concomitant disorders (tetrachlorethylene, emetine, carbarsone, chiniofon, diodoquin and atebum [mepacrine]) had no action upon the coccidia, which continued to produce oöcysts. C A Hoare

MATSUBAYASHI, H & NOZAWA, T Experimental Infection of *Isospora hominis* in Man *Amer J Trop Med* 1948, Sept, v 28, No 5, 633-7, 2 figs

Human infections with *Isospora hominis* have been reported from Japan on six occasions since 1939. In two cases the infection was acquired in China, while the remaining four were of local origin. They were characterized by diarrhoea and various abdominal symptoms, without a rise of temperature. In order to observe the course of the disease, experimental infections of two volunteers were carried out, with oöcysts obtained from two different cases. The oöcysts were first washed by centrifugation and kept for more than 72 hours at 28°C, until sporogony was completed.

In the first experiment, a volunteer (one of the authors) ingested about 3,000 oöcysts. Eight days later symptoms of diarrhoea developed and there was a rise of temperature, the febrile condition lasting ten days, with temperatures above 39°C. On the following day the diarrhoea subsided but later the symptoms returned and were especially pronounced on the 17th day of the infection after which they disappeared completely. Starting from the 9th day of the infection oöcysts of *I. hominis* were discharged regularly for 32 days.

Thirty-three days after the cessation of oöcyst-production in this person, he and another volunteer swallowed about 2,500 oöcysts each. In the first volunteer no infection resulted, probably owing to immunity acquired in the course of the original infection. In the second volunteer the course of the disease was similar to that described above, but the symptoms were more severe and oöcysts were discharged in the stools for six days longer. In both cases the symptoms disappeared without treatment after termination of oöcyst production. C A Hoare

COCKBURN, T A *Balantidium* Infection associated with Diarrhoea in Primates *Trans Roy Soc Trop Med & Hyg* 1948, Nov, v 42, No 3, 291-3

[A most interesting account] In June, 1947, at the London Zoological Society's Gardens a *Macaca nemestrina* (pigtail monkey) suffered from

weakness, wasting and loose motions and a heavy infection with *Balantidium* was found. Mepacrine 0.1 gm. daily was given with temporary success but with some difficulty and carbarsone 0.26 gm. b.d. was substituted, in tablet and was eaten greedily with excellent results. Though no *Balantidium* was seen after 3 days treatment was continued for 12 days.

Examination of 45 Primates in the monkey house discovered 8 infected four had had diarrhoea for some months. Small animal were given carbarsone in the same dose as the petal monkeys, the larger ones double this dose, and the diarrhoea ceased in 24 hours. Symptomatic carriers were not treated. Three weeks later some of the latter developed the diarrhoeic symptoms, as did also 3 Drills (*Mandrillus leucophaeus*) 3 *Macaca nemestrina* a *Cercopithecus* and a *Cer. opellaeus*. Again carbarsone cured the symptoms in 24 hours. The mode of spread could not be determined with certainty. In the monkey house cases occurred in all parts and not in adjoining cages. Spread may have been by flies. Crab-eating monkeys, *Macacus irus* were not infected, nor the chimpanzees but the latter are isolated behind glass. (The author wisely calls his article *Balantidium* infection associated with diarrhoea [or itches] not "caused by" but the protozoan was probably causative since if usual causes dietetic, helminthic and bacterial were excluded.)

RELAPSING FEVER AND OTHER SPIROCHETOSSES

ROUSSELLOT R. & DOVOLOX RAYN S. Mire. Sur une souche de spirochètes isolée d'une gerbille iranienne *Tatera indica*. A strain of Spirochaetes isolated from a Persian Gerbil, *Tatera indica*. B. H. Soc. Path. Exot. 1948 v. 41 No. 7/8 453-63

A gerbil caught in the neighbourhood of Teheran and splenectomized, died of an intercurrent infect in fourteen days later. The inoculation of an emulsion of the heart, liver and kidneys of this animal into three splenectomized wild mice (*Mus musculus bactrianus*) was followed in them by the appearance of spirochaetes in the circulation after incubation periods of eight or nine days. Two white rats, one splenectomized, were inoculated with the same material and one became infected after fourteen and the other after sixteen days. Attempts to infect guinea-pigs were negative but white mice were found to be very susceptible with a mortality of more than 50 per cent. Normal rats were not readily infected but developed a latent infection which could be detected by inoculation of the brain into mice.

Attempts were made to cultivate the spirochaete in fowl embryos. Eggs were inoculated after 7 days incubation and examined a week later when the blood of the embryos was found to be swarming with spirochaetes. After three passages in eggs the organisms were still virulent to mice after six passages the results were negative.

The results of cross-immunity experiments show that this strain is distinct from *Spirochaeta duttoni* but whether it is related to *S. muris* found by Ratti in Persian field voles (see this Bulletin 1947 v. 44 87) or to other strains has not yet been determined.

LEPROSY

INNES, J R Leprosy in Uganda *East African Med J* 1948, Oct, v 25, No 10, 379-81, 1 map

The author refers to visits to Uganda by COCHRANE and by MUIR and quotes the former's estimate of leprosy in that country as being 20,000, or 5.4 per thousand of the population

The present author has recently examined 14,808 people in Uganda and found an incidence of leprosy of 5.4 per thousand, and he estimates the present number of cases in the whole country as being 100,000. The survey is incomplete, but there is a definite impression that the final figure will be higher than that of Cochrane

It was possible to examine population samples of 500 or over in areas throughout the country. Co-operation by the people was very satisfactory and the author points to its importance

Results are shown in a map, in a table of area incidence and in a detailed list of the numbers examined in each place, which varied from 114 to 1,530. The highest incidence was around Fort Portal, Masindi and Arua, in which areas it averaged 11.7 per thousand. The lowest figures were 6 per thousand in the Entebbe, Masaka and Kampala area and 1.9 per thousand in the Sese Islands

It is noted that lepromatous cases varied from 15 to 20 per cent. No case seen was under regular treatment. (There are 4 leprosy institutions in Uganda and cases treated by them and other agencies are stated not to exceed 3,000.) No tribe was found exempt, but incidence was heaviest near the Congo Border and less near the Sudan. Segregation is rare (though it appears to have been practised rigidly in the past) and many children are left in house contact with cases of leprosy. Many other diseases were prevalent among those examined and other skin diseases cause diagnostic confusion. Housing is inadequate to prevent the spread of leprosy and the decline in prevalence must partly depend on adequate accommodation with a high amount of cubic space per person. Dietary standards vary greatly and were not correlated significantly with leprosy. The high average humidity over most of the country favours a severe type of the disease; in the few dry areas it is mild and rare. Environmental factors, communications and greater movements of people seem to be aiding a slow increase in leprosy in Uganda. *H J O'D Burke-Gaffney*

MUIR E Leprosy in the British West Indies *Leprosy Review* 1948, Oct, v 19, No 4, 139-42

This is a report on a visit during 1948 to the West Indies. Leprosy is a major problem in Trinidad and British Guiana, with about 1,000 cases in each, but less important elsewhere. On visiting the Trinidad leprosarium after three years the author found that under sulphone treatment lepromatous ulcers had nearly disappeared and that lepromatous cases were progressing towards recovery; these would otherwise have reached a hopeless stage. Good results were also observed in Jamaica, with arrest of eye lesions. In British Guiana and elsewhere similar results had been obtained.

Control in the smaller islands was slight because the small numbers isolated do not permit proper care, on financial grounds, so a new policy is advised in their case, namely the abolition of leprosy asylums and trusting to the attractions of present-day treatment in the place of compulsion. For this purpose two of the medical staff of each island should be trained in carrying out the treatment at a suitable centre; they would then be responsible for effective prophylaxis and treatment in their own areas. All immigrants from endemic

countries and contacts should undergo periodic examination and receive instruction on the dangers of infection to others. Such measures are only advised where the incidence is slight, as being more effective and less expensive under such conditions than compulsory isolation.

L. EYRE

Row R. Further Observation on Symbiosis of Microorganisms in Culture with special reference to *Mycobacterium* in Leprosy. *Indian Physician*, 1948, Oct., v 7 No 10 235-8, 4 figs. (3 coloured) on 7 pls.

The author first states that he has confirmed his isolation in pure culture of acid fast bacilli from leprosy lesions in symbiosis with *Leishmania* organisms [see this Bulletin 1946, 43 1147]. He goes on to report attempts at its symbiosis with other non-pathogenic acid fast bacilli. For this purpose he planted in haemoglobinized saline a few drops of fluid from a leproma, together with a trace of a non-leprosy acid-fast bacillary culture and obtained a mixed growth of long and short acid-fast bacilli forming heaped-up orange-coloured colonies like those of the tubercle bacillus. As it was found to be very difficult to separate the two forms, he cultivated the tubercle bacillus itself in a layer of Sauton nutrient fluid in a flask and introduced into the flask a sterile Pasteur Chamberland filter bougie containing a small fragment of the spleen of a mouse well infected with rat leprosy bacilli so that the diffusible substances generated in the flask by *Mycobacterium tuberculosis* could reach the rat-leprosy bacilli within the bougie without the latter organism being contaminated. After four weeks at 37°C. the sparingly distributed longish acid-fast bacilli within the bougie were planted out on glycerinated potato and on Sauton culture fluid for control. After eight weeks a small yellow patch developed on the potato surface as a pure culture of an acid-fast bacillus, now perhaps a little shorter than the original. A control test showed the bougie to be bacteria-proof. The author concludes that acid fast *Mycobacteria* can be isolated in culture by symbiosis of leprosy material with culturable micro-organisms whether they are micro-bacteria or proteus in culture makes no difference. How far the cultures thus isolated by symbiosis from the spleen of a mouse infected with rat leprosy bacilli as also those isolated from human lepromata and rat leprosy by symbiosis with proteus will satisfy Koch's postulates is left for future investigation.

L. Rogers

LOWE J. COCHRANE R. G. FITZ G. L. FIDANZI, E. P. DIAMOND JRA.
The Evolution of Leprosy and Leprosy Control. Correspondence. *Leprosy Review* 1948, Oct. v 19 No 4 143-54 (14 ref.)

This correspondence records the opinions of several experts on the vexed question of the evolution and control of leprosy and is designed to bring out the present confusion due to various classifications of the disease. Lowe maintains that changes from the tuberculous to the lepromatous form are extremely rare but in some cases mixed histological changes are seen. These lesions have a tendency to become lepromatous with negative lepromin reaction. COCHRANE states that "to base the diagnosis of a tuberculous lesion mainly on histology will lead to gross errors." He also has adherence to the current classification. He also holds that there are two clinical types of tuberculous leprosy with well-defined lesion and healing in the centre and (2) with less distinct borders, irregular edges, frequent reactions and a tendency to become lepromatous with negative lepromin reactions. The latter should be classed as borderline or indeterminate cases. FITZ writes on his experience at Carville (U.S.A.) where he has seen both tuberculous and lepromatous appearances together in the same patient and thinks that they may develop in either direction. He suggests that in each

cases the immunological status may be ill-defined, with some admixtures of types, but as they grow older the lesions become fixed to one type or other. More histological studies of the evolution of early cases are required. FIDANZA of Argentina thinks that the disease always begins as an undifferentiated simple inflammatory lesion and the later development depends on the degree of resistance. The lepromin test provides a valuable aid to classification, the most frequent change being that from a negative lepromatous to a positive reaction after prolonged energetic treatment. No type is immutable, but a direct change from one polar type to another is a rare exception. Dr DHARMENDRA from his Calcutta studies concludes that a change from tuberculoid to lepromatous type is rare and that the confusion is due to two different interpretations being given to the term tuberculoid, which should be restricted to cases showing only typical tuberculoid histological changes.

LOWE, J. Sulphone Treatment of Leprosy. *Leprosy Review* 1948 Oct, v 19, No 4, 129-38 [18 refs.]

ALDERSON, S. Physical Therapy in Leprosy. *Leprosy Review* 1948, Oct, v 19, No 4, 120-29

This paper deals with the physical treatment of crippled nerve cases in Nigeria by a B.E.L.R.A. worker, this has hitherto been neglected in British tropical countries, although these constitute a large proportion of advanced leprosy cases in which drugs have little place. In two-thirds of the patients, both arms are usually affected and at the Uzuakoli settlement 378 of 673 examined showed such lesions. Trophic changes were especially common in children, but many of the cases at all ages were in a fairly early stage with only slight wasting. Exercises are of great value in such cases, for the details of these the original paper should be consulted and also for simple forms of apparatus which have been found useful. Heat treatment is also useful and is best applied by means of baths of heated hydnocarpus oil, followed by massage for five to fifteen minutes, consisting of effleurage, kneading and friction applied to the whole hand and later to the ulnar border of the forearm. Active finger exercises follow. Suitable patients were trained to assist in carrying out the treatment after a European expert had examined the patients and given written instructions for it.

Occupational therapy by means of a specially designed simple hand loom proved effective especially in children, who co-operated best. Illustrative cases of the benefits are given. Exercises, based on notes by Dr RYRIE, for both hands and feet proved of value. When an affected nerve is acutely painful, injection therapy or an operation should precede physical therapy.

HELMINTHIASIS

COWPER, S. G. The Effect of certain Inorganic and Vegetable Substances on the English Pond Snail *Planorbis corneus* (Linné, 1758). *Ann Trop Med & Parasit* 1948, Sept, v 42, No 2, 119-30 [20 refs.]

The author tested the comparative molluscicidal effects of a variety of substances by exposing the English pond snail, *Planorbis corneus*, to them in various dilutions and for various durations.

After a review of part of the literature dealing with snail control with special reference to use of copper the results of tests with certain copper salts are described and tabulated. Copper acetate killed snails in 48 hours at a dilution of 1 p.p.m. copper chloride at 5 p.p.m. in 74 hours the less soluble copper carbonate was toxic at 5 p.p.m. It is remarked that *P. ovum* appeared to be more resistant than *Balanus* and *Physopsis* to copper salt judging by comparison with previous workers' results.

A series of eight different copper ores was also tested against *P. ovum*. These were ground up and samples of 5 gm. were suspended in paraffin-oil bags in the vessel containing the live snails. The best result was obtained with ores containing malachite which proved toxic to snails at a dilution of 1.25 gm. per litre. The toxic effect of ores is much less than that of the soluble copper salts, but they are thought to justify further trials in the field.

Extracts and preparations of a number of tropical plants were obtained mainly by boiling the leaves and the filtered liquids were tested against *P. ovum*. The action of extracts of *Eucalyptus* and *Sapindus* was almost negligible. In *Balanus Randi* and *Quillaja* a molluscicidal principle was demonstrated while extracts of *Tephrosia* leaf were effective only in high concentrations over long periods. The effects of saponin (Merck) were variable and in high dilutions had only a slight toxicity to the snails.

KIRKALDY WILLIS W. H. Cystoscopy in the Diagnosis and Treatment of Bilharzia Haematobium Infection. *East African Med. J.* 1948, Sept. v. 23 No. 9 333-61 13 coloured figs. on 3 pls. 89 refs.

The author since 1911 has been interested in cystoscopy in East African hospital practice. He has endeavoured to determine the value of this procedure in the diagnosis of urinary schistosomiasis and its differentiation from the changes in the bladder resultant on other forms of urogenital disease. He lists in considerable detail with illustrative cases the cystoscopic changes observed in Kenya Africans (*Algeriama* tribe) suffering from urinary schistosomiasis and from a wide variety of other bladder conditions. Cystoscopy he concludes is indispensable in the diagnosis and as a control after the treatment of urinary schistosomiasis.

[This paper does not lead itself to summary. It contains a great amount of information, ranges over a very wide field, and the references are numerous. It should be consulted in the original by those interested.]

A. R. D. ALLEN

GELFAND M. The Diagnosis of Schistosomiasis. *East African Med. J.* 1948, Sept. v. 23 No. 9 367-71 13 refs.

A conclusive diagnosis of schistosomiasis is dependent on recovery of the ova of the parasites in many cases this is difficult. The intradermal test for diagnosis is not specific, and both false positive and false negative reactions are common. Eosinophilia is of inconclusive value in diagnosis as is the Karmoljagi test.

Schistosomiasis due either to *S. haematobium* or *S. mansoni* should be suspected in those who have been at risk of infection and complain of constitutional symptoms—loss of weight and appetite, dyspepsia, turbid urine, flatulence, debility, inability to concentrate and cough—even in the absence of the classical manifestations of the disease. Examination of single specimens of urine or of stool for ova is usually inadequate; repeated examination may be necessary to reveal the characteristic changes occurring in the specimens.

and to demonstrate the presence of ova *S. mansoni* ova, in Southern Rhodesia, have been found in rectal biopsy snippings in sixty per cent of those passing eggs in the stools. In some cases of negative stool examination a diagnosis has been established by biopsy. Negative rectal snips and repeated stool examinations indicate reasonably conclusively an absence of *S. mansoni* infection. *S. haematobium* ova will not infrequently be found in rectal snippings, either alone or in association with those of *S. mansoni*, but they are very rarely found in the stools. Forty per cent of cases of *S. haematobium* infestation yield positive rectal biopsies.

Cystoscopy is of value in the diagnosis of urinary schistosomiasis. Even in the absence of visible abnormality (30 per cent of cases) bladder biopsies yield *S. haematobium* ova in a high (90 per cent) proportion of all cases of *S. haematobium* infection. *S. mansoni* ova are very rarely seen on bladder biopsy.

Radiography is a rather neglected method of diagnosis in urinary schistosomiasis. In 15 per cent of Africans [with *S. haematobium* infection] calcification in the bladder can be seen. The shadow is usually linear; it may be short, narrow, and faint, or it may be a complete circle resembling a foetal skull. In addition to the linear outline calcified striations or irregular calcified masses may be seen. In a small proportion of cases the ureter, especially in its lower third, can be seen outlined. In Europeans radiographic changes are far less evident, possibly owing to their lighter infestations.

Intravenous pyelography is of limited value and should be reserved for those cases with suspected ureteric complications; in these it may be found that the ureter is tortuous, elongated, and dilated, usually in its lower half.

I R D Idams

GELFAND, M. The Diagnosis of Schistosomiasis In Southern Rhodesia by the Rectal Biopsy Technique. *Trans Roy Soc Trop Med & Hyg* 1948, Nov., v 42, No 3, 283-6

The author discusses the various methods of diagnosis of intestinal schistosomiasis and refers at some length to the literature on the subject, especially in regard to the development of the technique of rectal biopsy. All the papers quoted have been abstracted in this *Bulletin*.

He then gives his own recent experiences with the use of rectal biopsy in the case of young adult Africans in Salisbury, Southern Rhodesia. The cases were divided into (1) those passing *S. mansoni* ova in the stools, but no *S. haematobium* ova in the urine; (2) those passing *haematobium* ova in the urine, but no *mansoni* ova in the stools, and (3) those showing no ova on microscopical examination of stool and urine (usually only one specimen of each was examined).

The patients were prepared as for sigmoidoscopy, with a saline enema (1 pint) beforehand. This rendered examination much more simple. After insertion of the sigmoidoscope a snip was taken from the first right dorso-ventral valve. The instrument was passed to the second valve of Houston and another snip taken from there. Finally, one or two snips were taken from between the two regions, generally from a haemorrhagic focus or other suspicious area. Bleeding was slight, but the snip was somewhat painful at the time. The snippings, which were only about 2 mm in size, were teased in water on a slide and examined with a low-power objective.

While the author did not obtain as high a percentage of positive results for *S. mansoni* in the rectum as did other workers, ova were found in most patients passing them in the stools and even in those passing no ova of any kind either in stool or urine. Nevertheless, stool examination should not be omitted, as even when ova are passed, biopsy may be negative.

An interesting feature was the finding of *S. haematobium* ova in rectal snippings alone or with *S. mansoni*. The author points out that ova of *S. haematobium* are often deposited in tributaries of the inferior haemorrhoidal vein. They do not always appear in the stool but have been reported not infrequently (see this Bulletin 1937: 1: 34-39). In the author's own experience less than 3 per cent. of those harbouring *S. haematobium* pass ova in the stool. He has, however, found ova of this species in 77 digested rectal specimens from 107 cases proved at autopsy to have vesical schistosomiasis. It is thus not surprising that these ova may be found in rectal snippings in cases of urinary schistosomiasis.

In the present series the author found ova in rectal snippings of 72 of 28 patients in group (1) above. 17 showed *S. mansoni* ova alone, 8 were dual infections and 7 were *haematobium* alone.

Fifteen patients in group (2) revealed 7 infections of ova in the snippings, all contained *S. haematobium* ova and two also contained *S. mansoni* ova.

Of 18 patients in group (3) 7 showed ova in the snippings, two were *S. mansoni* and five of *S. haematobium*.

The author considers that the biopsy technique is of added value in areas such as Rhodesia where both types of schistosome infection are present, or also GELF in this Bulletin 1939: 46-56. H. J. O'D. Brien-Gibney.

PIRAXO C. F. La infección unisexual producida por *Schistosoma mansoni* en condiciones experimentales. Unisexual Infection in Experimental Schistosomiasis *mansoni*. Archivos Venezolanos de Patol. Trop. y Parasit. Méd. 1938 Jan. 1: No. 1: 63-72. 11 ref. English summary.

It has often been reported and even confirmed experimentally that all the schistosome cercariae coming from a single miracidium are of the same sex. The author used for his experiments white mice and cercariae from *A. glabratus*, the intermediate host of *S. mansoni* in Venezuela in the dry season. He infected 96 animals, exposing them to 18 of these snails and later found 20 ova in the liver, 590 males in the portal veins, 72 of which mirrored sex otherwise no females. It is argued from this that larval form potentially masculine are more resistant during the dry season and that human infections acquired at such season are due to larvae predominantly of male sex. At 20 of these animals were subjected to infection in 10 snails taken from the rainy season. When examined later the liver was crowded with ova in the portal vessels were 205 males, 187 females and 16 not determined. Infection analogous to the above would be that the rainy season favours the production of larvae potentially female and that human infections acquired at such time likely to be both male and female.

The experiment was then carried a stage further. 1 animal was infected to cercariae from *A. glabratus* collected during the rainy season. At five when examined later showed many ova in the portal vessels. 4 male and 1 female worms in the portal vessels, altogether 14 males, 14 females, 120 not determined. Four animals were then subjected to infection in snails of the same batch which had been in the water at the same time as the first during which the volume of the fluid containing them had increased half by evaporation. When examined later one of the animals had ova in the liver, the other three had none. The first had 42 males and 10 females in the portal vessels, the other 23, 47 and 28 males respectively and no females. A study of much interest. H. H. W. J. O'D.

JAFFÉ, R Anatomia patologica y patogenia de la bilharziosis mansoni en Venezuela [The Pathogeny and Morbid Histology of Infestation by *Schistosoma mansoni* in Venezuela] *Archivos Venezolanos de Patol Trop y Parasit Méd* 1948, Jan, v 1, No 1, 32-62, 29 figs [33 refs] English summary

The author describes in minute detail the pathological anatomy and histology of the lesions produced in the different organs and tissues by the presence of *S. mansoni* and its ova—in the liver, the lungs, the myocardium, etc—and these are well shown in a series of photomicrographs. These are described in all reputable textbooks on tropical medicine and pathology and the knowledge is common to readers of this *Bulletin*.

In his discussion of the pathogeny the author breaks new ground. There is the local inflammatory reaction due to the presence of ova, but in addition there is a tissue reaction against toxic excretions of the parasite or its eggs, direct or by way of allergy, and this last may arise from allergy to the parasitic toxins or to products of the injured tissue. The myocarditis is thus attributed, and the cirrhosis of the liver, apart from the more localized pipe-stem cirrhosis, may be due to similar allergic reactions. Other lesions result from local accumulations of ova leading (in the intestine, for example) to necrosis and ulceration, but this seems to be uncommon in Venezuela, though reported as frequent in other countries. In Venezuela, the results in the large intestine are the production of a catarrhal condition with small haemorrhages.

MAYER, M Consideraciones sobre el tratamiento de la bilharziosis con preparados del antimonio (por las vias intravenosa, intramuscular, oral y rectal) [The Treatment of Schistosomiasis with Antimony, Intravenously, Intramuscularly, Orally and Rectally] *Archivos Venezolanos de Patol Trop y Parasit Méd* 1948, Jan, v 1, No 1, 120-43 [63 refs] English summary (4 lines)

The author introduces the subject by saying that his colleagues have asked for his opinion on the treatment of schistosomiasis by antimonials, so he is publishing observations based on what he has seen abroad. "It is not by any means my intention," he states, "to criticize the various forms of treatment adopted by medical experts." Then follows a discursive account of the use of antimony in tropical medicine. The first half deals with the use of tartar emetic in kala azar, the second reviews this salt, and foudrin and anthiomaline in the treatment of schistosomiasis. The opinions of more than 50 authors who have written during the past 30 years on the dosage and intervals between doses are quoted, but no original view is vouchsafed nor any account of original work.

ABDOU S & GRACE, H K Observations on the Late Results of Splenectomy for Bilharzial Splenomegaly *J Roy Egyptian Med Ass* 1948, Oct, v 31, No 10, 786-91, 4 figs & 1 map [11 refs]

Splenomegaly due to *Schistosoma mansoni* infection is common in Egypt. In 3 589 major operations performed at the Kasr El-Aini Hospital in the year 1936/37 there were 167 (4.65 per cent) splenectomies. In a village in Dakahlia province 344 persons between the ages of 8 and 20 years were examined for schistosomiasis and for splenomegaly, of these 269 (78 per cent) had schistosomiasis and 100 (29 per cent) had splenomegaly. Of the 100 with splenomegaly, 89 had schistosomiasis (84 *S. mansoni*, and 5 *S. mansoni* and *S. haematobium*), in the remainder no evidence of the infections was found. Treatment

with tartar emetic produced some shrinkage of moderately enlarged spleen and improvement in the general condition of these patients and the plasma from which some of them suffered disappeared as a result of it.

Observations were made on 42 patients splenectomized for splenomegaly from one year to 25 years previously (in 7 only of these cases was the diagnosis of schistosomiasis established microscopically). Thirteen of the patients were operated on by one of the authors, during the last 10 years of the 3 are still alive. Of the 5 that have died one died of portal thrombosis on the fourth day and four survived for two years after operation. Seven patients who had been operated on by other surgeons during the last 25 years are now dead. Of these one died recently of carcinoma of the liver 25 years after splenectomy. The general results of splenectomy were good: the splenomegaly and anemia from which the patients suffered disappeared and their nutrition and work capacity were restored; health was maintained in the absence of reinfection. The desirability of tartar emetic treatment in the early stages of splenomegaly is emphasized. It is important to give a course of tartar emetic treatment pre-operatively and re-treatment is necessary in the event of reinfection of individuals who have been splenectomized. A. R. D. (Lm)

BAUMAN, P. M., BENNETT, H. J. & INGALLS, J. W. Jr. The Molluscan Intermediate Host and Schistosomiasis japonica. II. Observations on the Production and Rate of Emergence of Cercariae of *Schistosoma japonicum* from the Molluscan Intermediate Host, *Oncomelania quadrasi* (Forst.). *Trop Med* 1948, July v 23 No 4 507-75 1 fig & 1 graph

"This investigation was conducted in order to obtain greater numbers of naturally shed cercariae for use in the laboratory of the Commission on Schistosomiasis in the Philippine Islands. The observations and experiments performed provided the following observations:

1. Alkaline water (optimum pH 7.6) was a critical factor in the natural release of cercariae of *Schistosoma japonicum* from the molluscan host *Oncomelania quadrasi* on Leyte.

2. Temperature variations of the water between 19 and 30°C. did not influence the release of cercariae from the naturally infected host *Oncomelania quadrasi*.

3. Artificial illumination and darkness were similarly unimportant factors; however the natural release of cercariae is of a definite nocturnal periodic nature. Cercariae were released in significant quantities throughout the early evening and continued emerging after midnight with the peak of production occurring from 9:00 to 11:00 p.m., steadily decreasing as daylight approached.

4. Naturally infected *Oncomelania quadrasi* will liberate cercariae on two to three successive nights and then an equally long period will pass before any considerable number of cercariae will emerge. Not a single known growth of *O. quadrasi* under observation for 30 days discharged cercariae continuously for more than three consecutive days thus indicating that the natural emergence of *S. japonicum* cercariae from the molluscan host is of a cyclic nature.

MAO, C. P. & LI, L. A Note on the Morphology of *Schistosoma japonicum*. *Proc Helminthological Soc of Washington* 1948, July 15 No 27 9 1 fig

As a result of the examination of several hundred adult *S. japonicum* including 15 Japanese and 8 Philippine specimens it is concluded that the length of the common caecum constantly occupies the posterior third of the body and the number of testes is invariably seven. Two exceptions in

the number of testes and several instances in peculiar morphology of the intestine are also reported"

ARENAS, R, ESPINOSA, A, PADRÓN, E & ANDREU, R M Fascioliasis hepática con carácter de brote epidémico [*Fasciola hepatica* Infestation as an Epidemic Outbreak] *Rev Kuba Med Trop y Parasit* Habana 1948, Apr-May, v 4, Nos 4/5, 92-7

In 1944 the authors were called upon to investigate cases of a disease characterized by digestive and hepatic symptoms accompanied by a high eosinophilia, occurring in San Cristobal, in the Province of Pinar del Rio. One doctor there had more than 40 such patients. Examination by the duodenal sound resulted in the finding of ova of *F hepatica*. The patients were accustomed to consume a good deal of watercress and examination of this showed the presence of *Physa cubensis* and *Lymnaea cubensis*, intermediate hosts of *F hepatica*.

Later, in 1947, in Pinar del Rio a "new disease" was reported the main symptoms of which were spasms of coughing and a high eosinophilia, thought to be due to filtrable virus. With assent of 20 local doctors, the authors went to the district with a view of seeing cases for themselves. The early symptoms were digestive and biliary, later pulmonary, cutaneous and nervous. They studied 52 patients. The usual history given was of pain in the abdomen, mostly in the epigastrium, with fever to 39-41°C, shivering and sweats, the pain persisted, with intermissions, for several days, the fever, shivering and sweating, worse in the afternoon and evening, also persisted, with remissions. Many complained of weakness, joint and muscle pains and allergic symptoms such as urticaria, pruritus and asthmatic attacks. Headache, insomnia, constipation and diarrhoea, together with a dry cough and a yellow discoloration of the skin were other symptoms, not always present.

Analysis of the cases showed that all the patients suffered from the abdominal pain in epigastrium or right hypochondrium, 45 had fever, intermittent or remittent, perhaps continuing for months, 43 had anorexia, 39 weakness more or less marked, 38 had enlargement of the liver, but not great except in a few. 33 had urticaria. Blood examination showed red cells between 3,200,000 and 5,140,000 per cmm with an average of 4,033,000, leucocytes ranged between the wide limits of 5,000 and 41,500, with an average of 16,500, eosinophiles might be as high as 81 per cent, but the average was 35. The duodenal sound was used in all 52 patients and ova of *F hepatica* were present in 22 of them, the amount of bile obtained being from 80 to 300 cc. Failure to find ova is ascribed, first, to the fact many were early cases and the parasites had not reached maturity, second, emetine hydrochloride had already been given. This had been done in nine patients. Forty-eight of the 52 owned to having eaten the suspected watercress.

H Harold Scott

KOURÍ, P Diagnóstico, epidemiología y profilaxis de la Fascioliasis hepática humana en Cuba [Diagnosis, Epidemiology and Prophylaxis of Infestation by *Fasciola hepatica* in Cuba] *Rev Kuba Med Trop y Parasit* Habana 1948, Apr-May, v 4, Nos 4/5, 77-87, 7 figs [52 refs]

Diagnosis of *Fasciola hepatica* infestation on clinical grounds is not very definite or conclusive, the symptoms of angiocholitis, and cholecystitis are common to bacterial infections of the bile-ducts and gall bladder and to gall-stones. Finding of the ova in the faeces is confirmatory, but they may be sparse and missed unless bile is obtained by the duodenal sound. Occasionally they are seen unexpectedly at operation or are not found until autopsy reveals

the presence of the worm. One symptom on which the author lays much stress is prolonged fever with high eosinophilia. Outbreaks of this have occurred in Pinar del Rio and La Villa. Laboratory diagnosis (apart from finding the ova in faeces or bile) includes biological reaction, intradermal reaction with extract of the trematode, precipitin test and de Wit's complement but these have not been long enough on trial to afford reliable results. The therapeutic test—the result of emetine treatment—is fallacious. Laccase is equally efficacious in amoebic hepatitis [see this Bulletin 1941 v. 25 no. 2].

Epidemiologically the Provinces of Pinar del Rio and Las Villas furnished most cases. Havana and Matanzas some but fewer. The author suggests the estimation of four indices for determining endemicity: 1. The *Hepatic Fasciola Index*—the percentage of slaughtered cattle found infected. 2. The *Ova-faeces Index*—the percentage of cattle passing the ova in manure and dairy herd, etc. 3. The *Malacological Index*—the percentage of *Pisum cubensis* and *Lymnaea cubensis* which act as intermediate host among the total snails and molluscs examined. 4. The *Cercarial Index*—the percentage of these intermediate host found infected with sporozoites (rediae and cercariae).

Prophylactic methods follow naturally from the foregoing and would comprise treating infected persons and cattle, boiling and filtering the drinking water, avoiding raw fruit and vegetables from infected regions, destruction of the intermediate snail hosts. The article has a bibliography of 52 references, 33 of which are by the author himself or with colleagues who have made fasciolosis in Cuba a special study. H. Harold Smith

Ledes, L. A. La *Railletomonis* es una endemia en el Ecuador. Nota apartada al conocimiento de la *Railletoma* (*Railletoma*) Equatoriana. [Identified by R. Kurius in Ecuador. Fresh Contribution on *Railletoma* equatoriana.] Bol. Su. Med. Quil Ecuador 1937 Jan. Feb. 3 No. 1, p. 41-9, 3 figs., 18 refs.]

There are several species of *Railletoma* which may infect man. *Railletoma madagascariensis* occurring not only in Madagascar but also in Sumatra, Borneo, Gambia, Formosa and the Philippines normally a parasite of birds. *Railletoma* (later named *Tricomicrifer*) found among children in Cuba, as two in Ecuador says the author, there are 6 or 7 species. Wherever he takes a new species. Their intermediate host is not yet determined, but may be small molluscs or beetles. They are common in the Province of Pichincha and they infect all races, white, coloured and half-caste, and adults. In children usually 6-8 worms are found in a patient. They set up gastrointestinal symptoms such as nausea, anorexia, colic and dysentery, or as a symptom headache, dulness, epileptiform or convulsive attack and changes of character and circulatory disturbances such as palmar anaemia sometimes with slight eosinophilia, precordial pain and arrhythmia. Treatment by Filix mas or by carbon tetrachloride gives good results in children.

The author gives a detailed description of the parasite. It is pear-shaped scolex, 500-700 μ by 400-500 μ with a characteristic arrangement of double row of hooklets at one end in number and 15-18 μ long, and 4-5 μ wide with an edging of three or four rows of small granular hooklets. The proglottides are nearly all broader than the length till the tail segments are reached. The genital pores are unilateral with a small one on the other side. The testicles are in number from 4 to 75 in all ages. The more or less solid ducts 0.5 mm with 20 μ diameter, possess an internal constriction, 10-20 μ most commonly eight. The uterus 10-15 μ long by 32-35 μ wide with two or three and very like the uterus of *Tricomicrifer*. H. Harold Smith

RISQUEZ-IRIBARREN, R & ORTIZ C, I Consideraciones con motivo del segundo caso de *Hymenolepis diminuta* en Venezuela [Remarks on the Second Case of Infestation by *Hymenolepis diminuta* in Venezuela] *Rev Policlínica Caracas* 1947, July-Oct, v 16, Nos 95/96, 201-14 English summary (7 lines) [32 refs]

In 1919 CUENCA reported that a child in Caracas, a patient of Dr Risquez, passed a worm which was identified as *H. diminuta*. This appears to have been the first recorded instance of this infestation in Caracas and that it is rare is evidenced by the fact that not until 1945 has another case been observed. This was in a child who was being treated for parasitism by *Ascaris*, *Trichuris* and *Necator*. The cestode passed was sent to the Smithsonian Institute at Washington where the diagnosis of *H. diminuta* was confirmed.

The remainder of the article consists of records by various authors who have examined faeces in considerable numbers during the past 25 years or so and the localities concerned, and gives in tabular form the numbers and percentages of *T. solium*, *T. saginata* and *H. nana* found—matters of local rather than of general interest.

HUNG, See-Lu & LI, Fei-Pai On the Egg Discrimination, Larval Culture and Infection Course of *Trichostrongylus orientalis* *Chin. Rev. Trop. Med.* 1948, Jan, v 1, No 1, 1-5, 1 fig

In 500 cases of ancylostomiasis which were diagnosed at Pehpei, the eggs of *Trichostrongylus* were found in 41 patients, all of whom were natives of districts in the lower valley of Fu-Kiang. A preliminary survey in these districts revealed a prevalent infestation with *Trichostrongylus*, ranging from 28.12 to 49.16 per cent. The abundant material provided by this survey enabled the authors to give a detailed account of the methods of differentiating eggs of *Trichostrongylus* from those of *Ancylostoma*, to devise a method of culturing *Trichostrongylus* eggs for the purpose of obtaining infective larvae, and to carry out experimental infections of rabbits with the larvae.

Measurements of 200 eggs of *Trichostrongylus* and *Ancylostoma* gave the averages $90.94 \times 45.12 \mu$ for the former and $64.89 \times 40.46 \mu$ for the latter. It is remarked that not only are the general dimensions different, but the length-width ratio is distinctive in the two species, for in 57.5 per cent of the *Trichostrongylus* eggs the length is twice as great as the width whereas in 100 per cent of *Ancylostoma* eggs the length is less than twice the width. Colour, shape, shell-thickness and degree of development of freshly-passed eggs are also contrasted.

A rather elaborate method of culturing faeces for infective larvae is described, which cannot be dealt with in detail in this abstract.

Experiments on the infection of rabbits with larvae of *Trichostrongylus* were carried out both orally and cutaneously. The oral method proved to be outstandingly the more effective of the two and it is suggested that human infection with *Trichostrongylus* may also be more readily incurred by oral ingestion of the larvae.

J J C Buckley

STRANG, C & WARRICK, C K Radiological Demonstration of *Ascaris* Infestation *Brit J Radiol* 1948, Nov, v 21, No 251, 575-8, 4 figs

For the diagnosis of ascariasis, radiography is seldom necessary, but it may be of value when for some reason, e.g. delayed parturition or the presence of male worms only, ova are absent from the stools. The worms are easily

demonstrable by serial radiographs of the abdomen at half-hour intervals. They may also be discovered accidentally during a barium meal examination for some other condition.

The radiological signs are (1) sharply defined band-shaped filling defects (2) linear shadows due to adherence of barium to the exterior of the worms (3) thread like shadows caused by the presence of barium in the enteric caeca of the worms and (4) evidence of disordered motility of the bowel.

The case of a ship's officer who stated that he had passed round worms in his stools is reported. He was symptom free and had no eosinophilia. Ova were found in his stools. Two courses of hexyresorcinol (1 gramme) followed in two hours by an ounce of saturated sodium sulphate on an empty stomach produced no worms. Two months later he still had ova in the stools. He was given 4 ml. of tetrachlorethylene and 1 ml. of oil of chenopodium after which he produced 5 dead larvae and subsequent stool examinations were negative.

He was examined radiologically before any treatment and after the hexyresorcinol. All the above-mentioned signs were demonstrated. At the second examination the worms were not demonstrated until the 5½-hour examination when a filling defect was observed in the ileum. At 6 hours barium was still adherent to the worms. [There are 4 very convincing illustrations of radiographs.]

J. E. Nafar

WILSON T. Bancroftia Filariasis. [Correspondence] The Roy Soc Trop Med & Hyg 1948 Nov v 42, No 3 305-8

This is a note in way of comment on Clayton LANK article this Bulletin 1948, v 45 887.

The author considers that conclusive proof of nightly parturition has yet to be found and that the facts could equally well be explained by the existence of a much longer period of gestation, expressed in days or even weeks but combined with a fair degree of synchronization between the adult worms and with expulsive parturition.

The evidence in favour of nightly birth and daily death of microfilariae is as yet not sufficiently conclusive.

The author notes that the youngest reported blood infection was a child of 14 months but he himself discovered a child of 13 months infected with W. malayi.

P. Marion Dale

MONTESTREUC E. A propos de l'index filarien à la Martinique (Il s'agit de la lymphangite endémique de pays chauds. The Filaria Index in Martinique (Il bancroftia) and Endemic Lymphangitis of Warm Countries.) Bull Soc Path Exot 1948 v 41, No. 3 6 372-3.

FLOCH and LAJOUX this Bulletin 1947 v 44 922 state that they cannot accept the filarial aetiology of tropical lymphangitis. This confirms with the present author's opinion expressed twelve years ago this Bulletin 1934 23 [27] in which he suggested that the filaria only plays a preparatory role by damaging the lymphatics.

The percentage findings in microfilaria surveys in various workers in Martinique through the last twenty-five years have been 5.47 in 1913, 37 in 1917, 18.6 in 1934, 1.75 in 1939 and 14.3 in 1945. It does not show the significance of these variations.

In the discussion Dr H. GALLIARD pointed out the fallacy of accepting the microfilaria index as evidence of the extent of filarial infection in a locality and quoted the American experience in which leprosy showed adult filaria in

many persons who had no microfilariae in their blood. The figures quoted above were also subject to variations of technique, to selection of population groups, and to the effects of patchy distribution.

On the subject of aetiology of lymphangitis of warm countries, he said it was not a question of being exclusively caused by bacterial infection or exclusively an allergic or a toxic manifestation—it was a question of the stage of development. The worm causes a loss of vitality of the local tissues and complications follow. It was possible that tropical lymphangitis was a distinct clinical entity, but that it was necessary to prove that no adult filariae were present; the absence of microfilariae was not sufficient. Again, it was a fallacy to suggest that because lymphangitis was uncommon in certain filaria-endemic areas it was not associated with filariasis. In different regions different clinical manifestations were found to predominate; this was possibly a human factor, as suggested by Buxton, or a parasitic one, there being different biotypes of filariae of which *W. malayi* was an example. L. E. Napier

STEFANOPOULO, G. J. & SCHNEIDER, J. Essais de traitement de la filariose à *F. loa* par la 1-diéthyl-carbamyl 4-méthylpipérazine [Treatment of *Loa loa* Infections with Hetrazan] *C. R. Soc. Biol.* 1948, July, v 142, Nos 13/14, 930-31.

Hetrazan (1-diethyl-carbamyl-4-methylpiperazine) has been used with success in the treatment of human filariasis (*Wuchereria bancrofti*) by SANTIAGO-STEVENSON and his colleagues [this *Bulletin*, 1948, v 45, 353]. The results obtained encouraged the authors to try this drug in filariasis due to *Loa loa*.

They used it (the citrate salt) in the treatment of 20 cases of *Loa loa* infection of variable duration and symptomatology. In three cases, the essential symptom was obstinate pruritus. There was always an eosinophilia, from 15 to 60 per cent. In seven cases, microfilariae were found in the peripheral blood and in all the other cases the clinical diagnosis was confirmed by the intradermal test. The patients were all adults.

The dosage given was 3 to 6 mgm per kilogramme body-weight, daily, by mouth, for 7 to 10 days. Within the first hours of treatment some subjects showed superficial reactions, a sensation of subcutaneous "creeping," temporary exacerbation of pruritus, or fugitive oedema, and in one case a generalized erythema. Rarely, there were a generalized reaction, nausea, arthralgia, diarrhoea and fever; all these reactions disappeared within 48 hours.

Within 48 hours all symptoms disappeared; in some cases, especially where there was pruritus, the improvement was spectacular. At the same time the microfilariae disappeared from the peripheral blood. In one case only were they found after 7 days of treatment. The worms tended to appear under the skin or mucous membranes (conjunctiva) and were sometimes eliminated spontaneously, or the dead worm formed a subcutaneous nodule without any oedema.

In some cases the symptoms disappeared for 2 to 4 months, but more often the improvement was transitory and after a few weeks of remission the symptoms returned in a less severe form. However, in nine cases it has been possible to effect an apparently complete cure by giving 2 to 4 courses of treatment of daily doses of 0.4 grammes for 10 days each, with intervals of 3 to 4 weeks between the courses.

The authors have had experience in the treatment of filariasis for 15 years, but this is the first drug that has given consistently good results.

L. E. Napier

TRENT Sophie C. Anthiomaline and Neostibosan in the Treatment of Filariæ (*Dirofilaria immitis*) Puerto Rico J. Pub. Health & Trop. Med. 1944 Mar., v 23 No. 3 311-60 3 charts & 1 fig. Spanish edition 319 [Refs. in footnotes.]

After treatment with anthiomaline a trivalent Sb compound reduction of disappearance of microfilariae in various filarial infections has been reported (this Bulletin 1940 v 37 656 1941 v 38 151 1945 v 42, 3). The effect of this drug on the microfilariae and adult forms of *Dirofilaria immitis* in naturally infected dog was therefore investigated. After microfilariae counts had been performed in 6 dogs for some days to note the variations in number present the animals were treated with 0.8 mgm. Sb per kilo intravenously till the parasites disappeared from the blood, which occurred in 10 to 22 days. The dose of Sb required to cause disappearance appeared to be unrelated to the numbers of microfilariae originally present. Two further courses of the drug were then administered and over a subsequent period of 1 week no parasites were found in blood. Changes in their structure or motility had not been observed during treatment. Six other naturally infected dogs served as controls in these experiments. In one treated dog autopsy was performed 1 day after disappearance of microfilariae and fragmented forms of the latter were seen in the tissues of blood vessels in lungs and in kidneys apparently being ingested by phagocytes. The drug which was non-toxic in the above doses therefore appeared to be rapidly effective against these young forms. The chief pathological lesions found in the remaining 5 dogs were in lungs and kidneys. Of 26 adult worms found however only 10 were dead and in them few pathological lesions were present. Developing forms however were generally absent from the uterus and, in the male, spermatozoa appeared to be affected. The author doubts the value of anthiomaline against the adult worms.

Neostibosan a pentavalent Sb compound has also been stated to be active against various microfilariae (this Bulletin 1940 v 37 836 1945 v 42 196 1948 v 43 54). Its effect was therefore studied above in the same infection in 6 dogs. In a first course of therapy 10 mgm. Sb per kilo were given 5 times weekly for 14 doses. At the end of 11½ weeks microfilariae were still present but in greatly reduced numbers. Re-treatment was begun 1 week later as symptoms became apparent and were followed by the death of some dogs. At the end of a further period of 1 week microfilariae were absent from the blood. Results showed however that neostibosan was not effective against the adult worms since 63 of 71 worms found at autopsy were male and ovaries and testes were normal. J. D. Hall

DUBOIS A. Notes sur la partion de *D. streptocera* à l'ouest de l'Algérie (Distribution of *Diptera* species etc. extra in Pawa. An. n. 1) J. d. Zool. 1914 June 30 28 v 1 151-3

As a result of skin examination on a limited number of individuals from various localities in Pawa, the author concluded that infection with *D. streptocera* has a wide distribution in that region and that it occurs in parts of different kinds of country including forest woodlands and in arid and semi-arid as well as in marshy country. The most widely distributed biting insect is *Culex* which is common in some places and less common in others while *mosquito* was absent or rare in the latter part of the region. Dissection of small numbers of *Culex* and *Aedes* mosquitoes proved negative but *Culex* is suspected to be the transmitter. J. J. C. Butler

PERRY, W L M A Case of Dracontiasis [Memoranda] *Brit Med J* 1948, Dec 25, 1107

An African male of 26 presented with a painless lump in the left groin, of 4 years' duration. Examination revealed a small easily reducible indirect inguinal hernia, not extending into the scrotum. No parasites were found in blood films, but there was an eosinophilia of 8 per cent.

At operation, the grossly thickened and fibrosed hernial sac was found to contain part of a female guinea-worm, the head and some 5 cm of its body were free in the lumen of the sac, the remainder being embedded in the wall. The worm was drawn out intact by steady traction. Convalescence was uneventful.

The unusual site of infestation caused a careful identification of the worm to be made. It was 23.7 cm in overall length, with a mean diameter of 1.4 mm. The body was an elongated cylindrical cord with a rounder anterior end and a hooked posterior end. The mouth parts and genitalia were typical of *Dracunculus medinensis*. The worm did not appear to be gravid and no male was found.

Despite its smaller size, the worm was otherwise characteristic of *D. medinensis*. There seems to be no previous record of this worm occurring solely in a hernial sac.

H J O'D Burke-Gaffney

DEFICIENCY DISEASES

NICHOLLS, L The Signs of Malnutrition and the Significance of them in Public Health Practice *Med J Malaya* 1948, June, v 2, No 4, 247-50

Extreme and florid forms of malnutrition such as beriberi and pellagra have recently received much attention from clinicians and research workers, as have such subjective manifestations as 'burning feet' and night-blindness. There are a number of relatively minor blemishes, found in high incidence among the malnourished, which may readily be detected in rapid examinations and which can provide valuable information in clinical survey work.

The aetiology of these minor signs, affecting mainly the skin, eyes and mouth, is as yet by no means certain, as multiple deficiencies and even non-nutritional causes may contribute to their production.

Among the signs most frequently attributed to vitamin A deficiency are thickening of the bulbar conjunctiva with or without Bitôt's spots, keratomalacia and follicular keratosis. Among the manifestations believed to be due to deficiency of riboflavin and allied factors are hyperaemia with vascularization of the cornea, cheilosis, angular stomatitis and a variety of tongue changes.

Hypochromotrichia, dry staring hair, seborrhoeic and mosaic skin and folliculosis are signs almost invariably associated with malnutrition, but of which the exact interpretation is still obscure.

The author emphasizes that, even in the case of a sign known to be usually associated with a specific deficiency, there may be other contributory causes which may alter the clinical picture.

[There is one point in this valuable paper with which some clinical nutritionists will disagree: the term 'permanent goose flesh' is suggested as synonymous with 'phrynoderma'. This was clearly not the intention of the original proposer of the term (PLATT, *Brit Med Bull*, 1945, v 3, 179) and the two conditions are certainly clinically, and probably aetiological, distinct.]

DARTON J. FIDDLAY C. M. & WARD R. D. A Note on Vitamin B Complex Deficiency States among Africans in the Gold Coast. *Trop. Med. & Hyg.* 1949 Nov. v. 4, No. 3 277-82, 1 graph

Five cases of optic atrophy apparently of nutritional origin occurred in African soldiers who for prolonged periods had lived predominantly on white rice instead of on their usual diet of cassava, yams or millet. All had impaired visual acuity, changes in appearance of the fundus and grossly contracted peripheral fields; one had generalized polyneuritis. Biochemical investigations revealed increased level of bi-sulphite-binding substance (BBS) in the urine and a low vitamin B₁ excretion.

These findings stimulated investigation into nutritional status of other Gold Coast soldiers and groups of the civil population. Slight evidence of optic atrophy was found in two other soldiers who had also been living on a rice diet, with associated biochemical evidence of a vitamin B₁ deficiency. There was a satisfactory response to high dosage of vitamin B₁.

Although numerous stigmata of B complex deficiency were found in African civilians, no cases of optic atrophy were discovered.

The soldiers living on a diet of the pattern normally consumed in the Gold Coast were free of deficiency signs which suggests that it is possible to obtain a satisfactory diet from locally available foodstuffs.

[There seem to be important differences between the syndrome here described and that which occurred commonly in the Far East, particularly among prisoners of war. In the latter cases contraction of the peripheral field was absent and the characteristic field defect was a central or paracentral scotoma. Vitamin B₁ was found to be ineffective in treatment even in early cases. SUTHER (this Bulletin 1947 v. 44 674) described the occurrence of amblyopia in over 30 patients who were under treatment with vitamin B₁ for beriberi at the time of onset. Moreover in most of the groups studied, there was a far closer relationship between amblyopia and such deficiency manifestations as oro-genital syndrome and burning feet than between amblyopia and beriberi.]

BURGESS, R. C. Some Aspects of Malnutrition in Malaya. *M. J. J. Malaya* 1948 June v. 2, No. 4 239-46, 5 figs.

Malnutrition is one of the most important causes of ill health in Malaya. The incidence of deficiency diseases was extremely high during the Japanese occupation but there has been no satisfactory improvement since 1945 in such respects, particularly in the case of beriberi. The improvement so far has been due to artificial and transient circumstances mainly the importation of Australian wheat.

Surveys have recently been undertaken of nutritional status in rural areas in Malaya embracing clinical, dietary, sociological and economic aspects of the problem. Data derived from clinical examination, height, weight, blood data and talc saturation indicate deficiency in almost all of the subjects and these are confirmed by dietary survey.

Poverty is the main cause of the poor dietary intake. It can be shown that protein and calorie intakes are directly related to the money available to the family for expenditure on food. Vitamin A and riboflavin intakes, on the other hand, largely uninfluenced by economic factors, and their deficiency in the diet is mainly a matter of ignorance, prejudice and the unavailability of foodstuffs rich in these nutrients.

As the economic side of the survey showed that the money spent on food in most families is over 80 per cent of the total expenditure, the problem is

clearly an economic one, and can only be solved by country-wide measures of increased and better food production, education and economic betterment

SPRUE

PRUSS J Sprue Diagnosis and Differential Diagnosis *Indian Physician*
1948 Oct \ 7, No 10 265-72

BENAIM PINTO, H & ARENAS, J V Investigaciones sobre el sprue en Venezuela. Nota preliminar [Preliminary Study of Sprue in Venezuela] *Archivos Venezolanos de Patol Trop y Parasit Méd* 1948, Jan, v 1, No 1, 144-80, 13 figs [22 refs] English summary

A survey was made in Venezuela for possible cases of sprue and it was found to be present where it was thought not to exist

In one case especially, which was studied in detail, the authors found macrocytic anaemia, with megaloblastic marrow, steatorrhoea, cachexia, glossitis, asthenia, and oedema, flat glucose tolerance curve, normal bilirubinaemia and normal gastric acidity. The jejuno-ileum was filled with gas and skiagraphy presented the picture of marked dilatation with abnormalities of the mucous folds. These symptoms appeared in a hitherto apparently healthy young woman after delivery. In association with sprue, the authors found two other syndromes: one a mild chronic nephritis, the other an enlargement of the liver probably due to previous amoebiasis or schistosomiasis mansonii

GARCIA LOPEZ, G, MILANES, F, LOPEZ TOCA, R, ARAMBURU, T & SPIES, T D The Maintenance of Patients with Tropical Sprue by means of Massive Doses of Synthetic 5-Methyl Uracil (Thymine) *Amer J Med Sci* 1948, Sept, v 216, No 3, 270-74, 4 figs

It has now been amply demonstrated that synthetic 5-methyl uracil (thymine) is capable of producing clinical and haematological response in patients with pernicious anaemia, nutritional anaemia and tropical sprue. It appears to have no special advantage over folic acid, and is effective only in several thousand times the dosage. Neither is it effective in preventing the onset of subacute combined degeneration of the cord in Addisonian pernicious anaemia, nor is it effective in retarding this process when once it has been initiated. The present study concerns itself with the maintenance of three selected patients, suffering from tropical sprue in relapse, for at least one year after the administration of large doses of thymine.

Three white Cubans (2 males and 1 female) were selected whose illness was characterized by the standard criteria already adopted in the previous studies by these workers.

After preliminary and thorough investigations each received 15 gm of thymine daily in two doses of 7.5 gm each. They were detained in hospital until they had recovered and their blood values had approached normal.

A definite haematological response ensued. Reticulocytosis commenced on the 4th or 5th day of therapy, reached its peak on the 8th or 9th, and was followed by a rise in the erythrocytes and haemoglobin. This was confirmed by sternal puncture, which showed almost complete obliteration of the megaloblastic arrest.

Clinical improvement coincided with the advent of reticulocytosis.

DAWSON J. FINDLAY G. M. & WARD R. D. A Note on Vitamin B Complex Deficiency States among Africans in the Gold Coast. *Trans. R. Soc. Trop. Med. & Hyg.* 1948, Vol. 42, No. 3 277-82, 1 graph.

Five cases of optic atrophy, apparently of nutritional origin, occurred among African soldiers who for prolonged periods, had lived predominantly on white rice in stead of on their usual diet of cassava, yams or millet. Others had impaired visual acuity, changes in appearance of the fundus and grossly contracted peripheral field. One had generalized polymyositis. Biochemical investigations revealed increased level of bisulphite-binding substances (HBC) in the urine and a low vitamin B₁₂ excretion.

These findings stimulated investigation into nutritional state of other Gold Coast soldiers and groups of the civil population. Slight evidence of optic atrophy was found in two other soldiers who had also been living on a rice diet with associated biochemical evidence of vitamin B₁₂ deficiency. There was a satisfactory response to high dosage of vitamin B₁₂.

Although numerous stigmata of B complex deficiency were found in African civilians, no cases of optic atrophy were discovered.

The soldiers living on a diet of the pattern normally consumed in the Gold Coast were free of deficiency signs, which suggest that it is possible to obtain a satisfactory diet from locally available foodstuffs.

[There seem to be important differences between the syndrome here described and that which occurred commonly in the Far East particularly among prisoners of war. In the latter case contraction of the peripheral field was absent and the characteristic field defect was a central or paracentral scotoma. Vitamin B₁₂ was found to be ineffective in treatment even of early cases. SUMNER (this Bulletin 1947 44 604) described the occurrence of amblyopia in over 80 patients who were under treatment with vitamin B₁₂ for beriberi at the time of onset. Moreover in most of the group studied there was a closer relationship between amblyopia and such deficiency manifestation as oedema, genital syndrome and burning feet than between amblyopia and beriberi.]

VENOMS AND ANTIVENOMS

SERGEANT Et Sérothérapie anti-scorpionique (Onchisme noir). Oliver atom médicaux reçues pendant l'année 1947. Treatment of Scorpion Sting with Antivenin. Report for 1947. (*Arch. Inst. Pasteur d'Algérie* 1948 Sept. 26 No. 3 253-8

During 1947 the Pasteur Institut, Algeria, has received reports of 98 persons stung by scorpions. In 348 of these the symptoms were said to be alarming and giving cause to expect a fatal issue. In 45 others they were serious but not alarming, and in 595 they were mild. In 43 instances only was the scorpion identified. 34 were *Proxenus* and four *Scorpius* was 11 and two *Buthus occiduus*. Special attention is drawn to patients with unusual symptoms or course.

(1) Three (one adult and two infant) already convalescent from scorpion infection of the antivenin. In one case the symptoms subsided in so short a time as half an hour. These three bring the total of such cases in the past 15 years to 151.

(2) One patient gravely ill after a sting on the head. The total of such is now 37 of which 31 were severe.

(3) Sensation of cold, like ice over the whole body in place of the usual sensation of burning at the site of the injury. One patient's temperature was down to 34°C.

(4) Five cases of acute oedema of the limbs, four children on adults. The last disappeared and could not be followed up. One child died and it is noted that the serum was given in too small a dose and not until 3½ hours after the injury was inflicted. The other three recovered.

(5) Two—an adult and a child of 12 years—with multiple stings, three times by the same scorpion. The former was stung three times on the calf and his condition was serious but he recovered. The latter was stung on the back and did not receive treatment until 24 hours later—the child died.

Stings in Northern Africa are commonly by *Prionurus australis*, those by *Buthus occitanus* are rare. Hence, the account of a European, 27 years of age, stung on the right thigh by one of them sent to the Institute is interesting. When seen an hour later, the patient was sweating and complained of sensations of alternating heat and cold, and of sialorrhoea. Ten cc of the antiserum were injected subcutaneously, 30 minutes later the symptoms were worse, with attacks of apnoea but without cyanosis, and a fatal issue was expected. Two hours after the stinging a second injection was given which brought about improvement. An hour later another 10 cc were injected and in 7 hours recovery was complete.

The author states that this is the sixth recorded case of stinging by *Buthus occitanus*, two did not receive the antivenin and died. [The others presumably recovered, the author remarks that in Europe no fatal case of stinging by this species is recorded.]

He stresses once again the precautions to be observed in the treatment of these accidents. That injection of the antivenin should be given as soon as possible, the first dose of 20 cc (2 ampoules) regardless of the age of the patient. If there is no improvement in an hour this should be repeated and even if recovery seems to be complete the patient should be under careful observation for several hours, as symptoms may return and call for more injections. Even if the interval between the infliction of the injury and obtaining the antiserum is a long one—up to 24 hours—recovery is still possible.

Summing up the results. Of the 348 cases regarded as severe 331 were cured (95.1 per cent) during 1947. Throughout the 12 years during which the serum prepared at the Institute has been used, 4,057 patients have received this treatment, 1,003 were in an "alarming even desperate" condition, and of these 923 (92 per cent) were cured. [For references to previous papers in this series, see this *Bulletin*, 1948, v 45, 463.] H Harold Scott

DERMATOLOGY AND FUNGUS DISEASES

REDAELLI, Piero & CIFERRI, Raffaele. *Le granulomatosi fungine dell'uomo nelle regioni tropicali e subtropicali*. [Fungal Granulomata of Man in the Tropics and Subtropics.] *Trattato di Micopatologia Umana*. Florence 1942. Vol 5, pp vii + 698, 2 maps & 195 figs (5 coloured) [50s.]

Although this book was published seven years ago, it contains an immense amount of factual information regarding medical mycology. It is inevitable that the rapid advance made during the war years should not be included, but the work covers a great deal of ground in respect of the material available at the time. In the General Section of the book, the first chapter deals at some length with climatic considerations, with special reference to equatorial zones and the former Italian East Africa. It also discusses relative incidence of fungal granulomata.

The second chapter discusses the pathology and morbid anatomy of human mycoses in the tropics and sub-tropics. The third chapter deals with the systematic classification.

The Special Section contains 12 chapters dealing specifically with the individual conditions, e.g. actinomycosis, rhinosporidiosis, coccidioidosis, various

blastomycosis, histoplasmosis, sporotrichosis, maduroomycosis, verrucous mycosis of the skin, and various miscellaneous mycoses.

Each condition is dealt with systematically and at length with descriptions of geographical distribution, aetiology, pathology, clinical features, diagnosis and treatment. Morphology and cultural methods are discussed and there are good and liberal illustrations of the fungi and the pathological and clinical lesions produced by them.

Each section contains an adequate and often very lengthy bibliography covering a wide range of the literature from many countries.

There is a subject index of more than 700 pages and an authors' index of 14 pages in which the widely international sources of the references are apparent.

This work should provide a great deal of information for medical mycologists, even without familiarity with the Italian language.

HOPKINS, J. C., HILLEGAS, A. B., LEDDY, R. B., REBELL, G. C. & CAMP, F.
Treatment of Hyperhidrosis and Symmetrical Lividities of the Feet. *Arch. Derm. & Syph.* 1945 May 1, 57, N. 3, 650-54, 4 figs.

In the course of a study of dermatophytosis among infantry troops at Ft. Benning, Georgia, the authors encountered numerous cases of severe inflammation of the feet which they attributed to hyperhidrosis. These cases were of two types—(1) diffuse hyperhidrosis in which cases in 3 cases of the whole foot occurred. In this condition the skin was often macerated and there was frequently erythema and oedema of the toes with fissuring of the interdigital webs and sometimes non-suppurative cellulitis of the toes. (2) Symmetrical lividities. These occurred in many men with and a few without general hyperhidrosis. The lesions consisted of sharply bordered plaques of white soggy skin surrounded by narrow violet-red borders. The plaques often appeared slightly raised, and were sometimes extremely sensitive to touch. They occurred most frequently on the sole of the heel and the head of the metatarsals but also on the plantar and lateral surfaces of terminal phalanges and anywhere where the shoe or a neighbouring toe exerted pressure.

In treatment the following preparations were found useful—

(1) Foot baths containing 4 per cent potassium alum seemed the most useful treatment for cases of diffuse hyperhidrosis with inflammation.

(2) A 4 per cent solution of formaldehyde painted on the affected areas gave the most prompt relief in cases of symmetrical lividity.

(3) For dressing denuded areas resulting from hyperhidrosis, tannic acid ointment seemed useful, especially 10 to 20 per cent tannic acid in a carbowax base.

(4) Where prolonged treatment was required, powders were more practical and probably of greater benefit. A powder containing 2.5 per cent exsiccated potassium alum and 5 per cent talc appeared satisfactory but the most permanent and decisive result was given by powders containing 5 per cent paraformaldehyde in talc or bentonite.

HILL, W. R., RUBENSTEIN, A. D. & HODGES, J. Jr. Dermatitis resulting from Contact with Moths (*Gn. & Hyalus*). Report of Cases. *J. Amer. Med. Ass.* 1945 Nov 6, 138, N. 10, 737-40, 1 fig.

Moths of the genus *Hyalosia* inhabit the tropical regions of America. During the daytime they are found on tree trunk, walls or fences while at night the females appear in large numbers at certain seasons and then mate in swarms. The authors describe how the crew of an oil tanker were exposed to moth which

swarmed on to their ship while it lay off the coast of Venezuela. Of 45 men exposed to the moths, 31 developed dermatitis of a papulo-vesicular or urticarial type. The eruption occurred not only as a result of exposure to moths but also after contact with moth-stained bed sheets. The diagnosis was confirmed by positive reactions to patch tests with moth hairs. *H T H Wilson*

CLARK, M. **Lymphostatic Verrucosis in the Fort Hall District of Kenya** *Trans Roy Soc Trop Med & Hyg* 1948, Nov, v 42, No 3, 287-90, 4 figs on 2 pls

In the last 3 years the author of this article has seen 200 cases of the condition described in Uganda by LOWENTHAL [this *Bulletin*, 1935, v 32, 182] as lymphostatic verrucosis. The patients were Africans who lived round the foot of Mount Kenya and Aberdare Mountain Range. The condition was recognized clinically by the following features: (1) oedema of the leg extending up to, but never above the knee, (2) a barnacle-like growth of the foot, (3) ulceration, usually starting at the toes, and sometimes becoming severe enough to necessitate amputation.

Although generally bilateral, the condition, even when far advanced, was not infrequently limited to one leg. The hands and other parts of the body were never involved.

Attempts to isolate a causal organism by inoculation to media and inoculation into rabbits were unsuccessful.

Although lymphostatic verrucosis is frequently confused with mossy foot, there are several fundamental differences between the two conditions. Mossy foot starts with a vesicular stage, is painful, and bleeds easily on slight injury, it attacks parts of the body other than the leg, and can be transmitted to rabbits.

The author was unable to find any evidence of filarial elephantiasis, which is an unknown disease in the Fort Hall district, or of yaws in any patient suffering from lymphostatic verrucosis.

Routine treatment consisted of scraping away the growth with a short amputation knife. Bleeding was slight after this procedure, the growth did not tend to recur, and permanent benefit resulted. *H T H Wilson*

ALEIXO, J & FURTADO T A. **Micose de Lutz de início possivelmente dentário (Relato de cinco casos)** [Mycosis of Lutz possibly of Dental Origin. Report of Five Cases] *Brasil-Médico* 1948, July, 17, 24 & 31, v 62, Nos 29, 30 & 31, 265-8, 6 figs. English summary (9 lines)

The epidemiology of South American Blastomycosis (Lutz's disease) is rather obscure. Lacaz cultivated the causative fungus, *Paracoccidioides brasiliensis*, on various vegetable materials including mushrooms, and the almost constant occurrence of early lesions of the disease about the buccal, lingual and pharyngeal mucosae and the tonsils lends credence to the view that infection is caused by chewing vegetable matter on which the fungus has been growing saprophytically. LACAZ and DE OLIVEIRA [this *Bulletin*, 1949, v 46, 84] have recently described a few cases in which the initial lesions occurred in the anal region and were attributed to the use of raw vegetable matter in attending to the toilet of the anus.

BOGLIOLO [this *Bulletin*, 1947, v 44, 349] described a granuloma of a tooth socket which was caused by *P. brasiliensis*, and the present authors have added five new observations suggesting infection in connexion with the teeth. In all five cases there was a history of severe dental disease, usually associated with pain, inflammatory swelling and ulceration, and all were treated by extensive extractions of the affected teeth, which were followed within a few months by active granulomatous ulceration which spread to the lips and neighbouring

extradural block. Healing within 7 days was nearly complete and the patient was discharged 11 days after block. [No mention is made of local treatment.]

Where skin anoxia is due to structural disease of the arteries sympathetic block cannot be regarded as being specific as the lumen of the affected arteries is probably incapable of much increase. The sharp rise in skin temperature following sympathetic block suggests that the released vessels are in a state of vasospasm.

The aetiology of tropical ulcer is summarized as Skin anoxia and infection. In difficult cases treatment should be given for both factors. C. F. Shelton

MISCELLANEOUS DISEASES

GALLIARD H. Myiasis humaine en Tonkin. (Human Myiasis in Tonkin)
Bull. Soc. Path. Exot. 1948, 41, No. 3, 423-33.

Fifteen cases of myiasis have been observed in the clinics of the Faculty of Medicine at Hanoi. Of these larvae were found in the external auditory meatus on five occasions, once in a case of otitis of the left ear, seven times in wound or ulcers of the legs or feet, once in an abscess of the hand, and once in an ulcer of the scalp. In the last case the larvae were those of *Wormphora* *f. senilis* and in all the rest *Chrysomya* *bezzii*.

The case of *S. fascicularis* infestation was that of a child of 1 month whose mother gave a history of furuncles of his scalp that opened spontaneously. Maggot were observed in the ulcers, these persisted despite treatment with 'home remedy'. When seen the child had two large oval ulcers (4 to 5 cm. with jagged edges) in the parietal region and several smaller ulcers on the occiput. There was a foetid purulent discharge, later the ulcers joined and a large area of bone was laid bare. The child's temperature rose to 39.6°C (103.5°F) and remained in the region of 38.0°C (100.4°F) for nine days. The ulcers were filled with larvae of *S. fascicularis* which were removed by means of forceps and an antiseptic lauge. At the time of discharge a week later the temperature was normal and the ulcers improved but not completely healed.

The second case described was that of an Annamite infant who was admitted to hospital with necrosis of the angle of the jaw. The wound was gangrenous and full of larvae. This condition was effectively treated but the child was brought back forty days after discharge from hospital with supra-clavicular adenitis. This improved on local treatment but the child returned a third time with a fluctuating and painful swelling of the gland which was finally opened four months and seven days after the child first came in and a dead but well-preserved third-stage larva of *C. bezzii* was recovered from the abscess.

The larvae of *C. bezzii* are not recognized in Africa or in the Philippines as infecting man but are only parasites of animals. L. E. Napier

PROTOZOOLOGY CENTRAL

ISHII N. Researches on the Chemotherapy of Protozoal Infections. J. *was*
Med. J. 1948 Feb 1, 1, No. 1, 30-51.

This paper describes the results of tests carried out with various compounds on various protozoal infections including human and bird malaria.

Trep duttoni and *Trypanosoma gambiense* infections of mice, kala azar of man and the striped squirrel and *in vitro* tests on *E histolytica* and *Trichomonas hominis*. The English is quaint and there are a number of errors in names and dates. No details are given of the tests, which appear to have been carried out on a very limited scale in man. Two substances, 1-sulphanilamido-3,5-dibromobenzene and its chloro analogue, not antagonized by *p*-aminobenzoic acid, "were applied for three tertian cases with desirable results." These substances, SN 187 and SN 2500 respectively, are described in the Survey of Antimalarial Drugs by WISELOGLE [this *Bulletin*, 1947, v 44, 1106]. Some substituted dihydro-cinchonidines (or cinchonines) showed promise in human malaria and also "modified atabrin" [mepacrine] in which the original side chain of the German product was replaced by

The latter was easier to make than atabrin and proved equally active in canary malaria. "The malaricidal action in five tertian cases was demonstrated with satisfactory results." A natural product from an Asiatic plant—cepharanthin—a benzyltetrahydroisoquinoline described by KONDO & TOMITA (*Arch Pharm* 1936, v 274, 65), was first used in the treatment of tuberculosis and is here described as a provocative for exoerythrocytic forms of plasmodia, through stimulation of endothelial cells whereby the exo-forms appear in the blood stream. In conjunction with standard antimalarial drugs it was reported to eradicate tertian [benign or malignant?] malaria infections. Two other related substances are stated to possess similar properties. A number of sulphonamides were found to be active against *Trep duttoni* infections of mice. Several oxyquinoline sodium antimony compounds (constitution not stated) showed activity against *T gambiense* in mice and *in vitro* against *E histolytica* and *Trichomonas hominis*. Activity is claimed for 4,4'-diguandinodiphenylsulphoxide in the trypanosome infection and in human kala azar. Other compounds found to be active against *E histolytica* were SN 187 mentioned above and also 3-carboxy-4-aminoazobenzene-4'-sulphonamide.

ENTOMOLOGY AND INSECTICIDES GENERAL

NATVIG, L R. Contributions to the Knowledge of the Danish and Fennoscandian Mosquitoes. *Culleini Norsk Entomologisk Tidsskrift* Oslo 1948, Suppl I pp vii+567, 148 text figs 12 pls & 1 folding map

The present book is a full-length monograph by a man who has evidently worked on the subject for a number of years and has given careful attention to all available sources of information. He is interested primarily in the thirty-five species of Culicine mosquitoes which occur in Denmark, Norway, Sweden and Finland. For these countries he gives detailed local records, outside that area he provides information of a more general sort relating to the same species. A considerable proportion of the mosquitoes of these northern countries have a very wide Arctic distribution in the Old World, several of them occur also in Northern America.

Fifty-five pages are given to an account of the external anatomy of Culicine mosquitoes. The treatment is full with a number of figures, a list of technical

terms and alternative terms used by other authors. Though the section is a valuable one may perhaps ask whether a general account of this nature could not be produced once and for all. It seems hardly necessary that all this information should be repeated as it tends to be in monographs dealing with monogonies of different parts of the world.

After giving a brief account of internal anatomy the author passes to general notes on the biology of northern Culicines. He deals with the type of water in which the different species breed and the association of one species with another. In discussing the feeding habit of adults he quotes the work of others who have shown that not only the males but the females of some Culicines may feed upon nectar in nature. He reaches the conclusion that females of all or nearly all these northern Culicines are bloodsuckers but does not go into the question whether the individual female can lay a small number of eggs if she is unable to obtain a meal of blood.

The transmission of disease by mosquitoes in Northern Europe is relatively unimportant. One should, however, remember that tularaemia is widespread and it appears from the work of Olin that without doubt the infection is occasionally transmitted by mosquito bites. Eosinophilic infection (the St Louis type and the equine) are not known from this area. Fowl pox occurs in Denmark and parasites of several "bird malaria" have been recorded from a number of species of birds in Sweden.

Much more important than the diseases is the mosquito plague, a general and very serious Arctic problem. The author has gathered together extracts from the works of many travellers and recounts his own experience. It is part of the work is most useful for it calls attention to a matter of considerable importance, the number of blood-sucking mosquitoes (hardly to be feared, they cause extreme discomfort by day and by night and may drive man or animals to frenzy, casualties occur owing to swollen hand and faces, fever and lack of sleep. The biological explanation of the immense numbers of mosquitoes is due to the work of the freshwater biologist Thienemann who pointed out that when the ground is frozen it is impossible for water to percolate downwards. When the surface of the ground thaws in the spring and in the summer the water must lie on the top or run over the top, and it may become very warm during the long days of the Arctic summer. For a brief account it gives rise to enormous numbers of adult Culicines, mainly species of *Aedes*. As to the source from which all these mosquitoes would normally obtain blood we are insufficiently informed. The present author does not accept the view of Thienemann that the insect feeds mainly on small rodents (voles and lemmings). He regards reindeer both wild and domestic as a most important source of blood for the mosquitoes but we feel that he hardly gives sufficient attention to the fact that there are many areas in the Arctic with abundant mosquitoes but no reindeer. As it stands he can only give a scanty record of record of mosquitoes feeding upon nestlings. The whole question appears to be one urgently requiring study. It is at least possible that in some of these species the female though willing enough to take blood, can lay a small number of eggs without having fed on blood.

The greater part of the book deals with taxonomy, including taxonomy and nomenclature and the literature of Scandinavian mosquitoes. The author gives some interesting notes on variability and on the seasonal abundance of mosquitoes, calls attention to the fact that in the mosquitoes there are a number of groups of very similar so-called "sibling" species. The systematic section covers thirty-five species of Culicines known to occur in this area. The few Anopheles mosquitoes are not dealt with, one may hope that these will be dealt with in a similar monograph in a similar manner. After reviewing the problem in a thorough manner the author discusses the complex question of the control of mosquitoes.

to geography and so forth. Here we find lists of the mosquito species which are known to occur in each of the countries under discussion together with their distribution outside Scandinavia. One list shows the species of this area and indicates which of them occur also in Siberia or in North America.

The monograph contains 148 figures, many of them dealing with points in the anatomy of larvae and adults. Some deal with breeding places and other biological matters and there are maps of the distribution of many of the species, and on matters of general zoogeographical interest. The paper contains a number of taxonomic keys. The general presentation is excellent. The English is always clear. There is an unusually full list of references and an index.

RICHTER, R. G. Encontro da *Chagasia rozeboomii* Causey, Deane e Deane 1944, no estado de São Paulo. [Presence of *Chagasia rozeboomii* in São Paulo.] Reprinted from *Malariaeologia e Doenças Tropicais* Rio de Janeiro 1948, July-Sept., v. 1, No. 1, p. 13.

The English summary appended to the paper is as follows —

In this article the Author refers to a new species, *Chagasia rozeboomii* Causey, Deane & Deane, 1944, found in State of São Paulo, Brazil.

SMITH, C. B. Commonwealth Air-Route Sanitation — a Suggestion. *J. Roy San Inst* 1948 Sept., v. 68, No. 5, 539-44. [12 refs.]

It has been established beyond doubt that many insects which are potential carriers of disease can be transported by aircraft without detriment to themselves to places where they could do great damage as for instance by the dissemination of yellow fever. The organizations concerned in the reduction of this risk are badly co-ordinated, too numerous and often have too parochial an outlook. The author recommends the creation of a high level authority of air sanitation consisting of a committee and a powerful executive staff with powers wide enough to ensure that disease vectors would not be carried on to aircraft rather than as at present to prevent them being brought off them. This would involve supervision of the sanitation of airfields in endemic zones and of the urban areas from which passengers come. In addition sanitary zones should be created co-terminous with the endemic areas of important diseases and a complete protective ring of 'sanitized' airports created within the zone and outside it so that the ports of embarkation and potential dissemination of disease vectors are protected not by quarantine but by sanitation. Further work should also be carried out on the disinsection of aircraft by residual insecticides.

CALIFORNIA MOSQUITO CONTROL ASSOCIATION. Proceedings and Papers of the Sixteenth Annual Conference of the California Mosquito Control Association held at Agriculture Hall, University of California, Berkeley California, February 12, 13, 14, 1945. [Edited by H. F. GAY & R. F. PETERS.] 89 pp. 4 figs. & 3 charts. 1945. Berkeley 1 California Post Office Box 649.

In California there are forty-one mosquito abatement districts covering some 16 000 square miles and others are in process of organization. On this work the above Association spends about \$7 000 000 annually and it is likely that this sum will be exceeded in the coming year. At this three-day meeting of the Association, papers were read by many authors and they are reported *verbatim* in this volume which also includes reports on the progress of mosquito control work in other parts of the U.S.A. A wide range of subjects is covered including some of local interest only and dealing with such matters as organization, administration, finance, legal matter and some of a technical nature. A short account is given of the inauguration in 1917 of a State Bureau of Vector Control which comes under the Department of Public Health. In this the author describes the scope and proposed activities of this Bureau and its relationship to local mosquito abatement organizations. A first list of vector-borne diseases to receive immediate attention by the Bureau includes encephalitis, fly-borne diseases, malaria, plague, "Q" fever, relapsing fever, Rocky Mountain spotted fever, tularemia and typhus fever.

Other papers are of more general interest and the fact that most of them are the results of practical experience in the control of mosquitoes and other arthropods adds to their value. Members plead for better diagnosis of malaria and improved methods of keeping records. The flight range of *Culex tarsalis* was discussed, method of dealing with noxious arthropods other than mosquitoes were described, and the importance of the selection of insecticides for particular purposes was stressed. The necessity for continuing the search for new insecticides was also emphasized in view of the resistance and tolerance of DDT and other substances indicated by the contamination of water, the effect on agricultural pests, the danger to fish and the DDT tolerance in certain flies. Other papers describe the application of insecticides from a machine mounted on a jeep, an aerosol generator, amphibian, helicopter, aeroplane spraying and the keeping of mosquito cultures in the insectary.

The importance of maintaining good public relations is pointed out even to the extent of doing extra work not strictly coming under the heading of mosquito control and in propaganda in newspaper, film and radio.

It is inevitable in a report of this kind that there should be some overlapping and repetition, but each author approaches his subject from his own angle and a wide view is thus given of the activities of this association. The conference appears to have been held in an atmosphere of friendly enthusiasm.

H. S. LEE

VANNOTE, R. L. Adult Mosquito Control a Useful Emergency Tool. *Mosquito News*, 1945 Mar., v. 5 No. 1 p. 17-2 figs.

The author is concerned with the protection of large highly-developed residential areas from mosquito nuisance. Circumstances in which the prevention of breeding by permanent means—the most desirable method, other method being brought into use to combat breakdown in the normal programme. The best auxiliary method are then those that produce immediate results.

Pyrethrum sprays applied to ground areas were a great advance. With the arrival of DDT the policy has been to treat the country across which mosquitoes

fly in large numbers by the application of DDT solution from aircraft, and to exterminate those that have reached residential areas by means of smoke from machines such as the Todd Insecticidal Fog Applicator *G Macdonald*

DICKINSON, W H, MERRITT, D & HOUGH, J Observations on a Tifa used by the Consolidated Mosquito Abatement District *Mosquito News* 1948, Mar, 18, No 1, 14-16

The authors' interest is to destroy nuisance mosquitoes, such as *Aedes* species, the breeding of which cannot be controlled, though it may be very extensive as on irrigated land. The Todd Insecticidal Fog Applicator was found to give very satisfactory results. The fog, allowed to drift over agricultural land where such breeding occurred, killed all adult mosquitoes through a strip a mile long, as laid by the machine on a truck, to a depth of one and a quarter miles. The average amount of DDT used was 0.04807 lb per acre thus treated, and the average cost for labour and material 11.5 cents per acre *G Macdonald*

MACCHIARLLO, A Siphonaptera de la costa sur-occidental de América. (Primera lista y distribución zoológica y geográfica) [Siphonaptera of the South-West Coast of America (First List and Geographical Distribution)] *Boletín Oficina Sanitaria Panamericana* 1948, May, 27, No 5, 412-60 [21 refs.]

Over the past fifteen years the author and his colleagues have examined 500,000 fleas during their work in Chile, Peru and Ecuador. From this work and from the literature, the author has been able to compile lists, which are given in full, of seventy-six species of fleas belonging to thirty-seven genera, and of ninety-six hosts, together with locality records which give their distribution in this part of South America *H S Leeson*

LORD, K A The Sorption of DDT and its Analogues by Chitin *Biochem J* 1948, 43, No 1, 72-8

RICHARDS and CUTKOMP (*Biol Bull Woods Hole*, 1946, 90, 97), have pointed out that there is a general correlation between the possession of a chitinous cuticle and sensitivity to DDT poisoning and also that chitin will sorb DDT out of a colloidal suspension. The author has made quantitative experiments which confirm this. Neither sand cellulose nor asbestos appreciably sorbs DDT and though there is some indication of sorption with sheep's wool it is very slight compared with chitin. These facts show that the sorption is not due to mechanical retention of DDT and also, since the cellulose molecule is very similar to that of chitin, that the action is physico-chemical or chemical and rather specific. Grinding of the chitin, which increased its surface area, also increased the amount of sorption, which is therefore a surface phenomenon. It was noted that sorption occurred rapidly at first and then apparently approached saturation. Tests with five DDT analogues (mainly corresponding to the compounds) showed no significant evidence of correlation between toxicity and degree of sorption *J R Bustine*

DE OLIVEIRA, S J & MOISSAHEM, I Ação do DDT (Diclorodifenil-tricloro-etano) sobre larvas e pupas de *Musca domestica* Linneus [The Action of DDT on Larvae and Pupae of *M domestica*] *Rev Bras Lepra Biol* Rio de Janeiro 1947 Mar, 7, No 1, 67-72, 4 figs. [Summary taken from *Rev Inst Med Biol São Carlos* 1948 Oct, 36 Pt 10, 157-8.]

In each of the tests described which were carried out in Rio de Janeiro in 1946, a jar or box was filled with fresh horse manure and left for four days, after

which these larvae of *M. sca domestica* L. in all instars were present. The manure which was about 18 in. deep was then sprayed with suspensions of a preparation containing 10 per cent. DDT (Neocid M) diluted to give 1:2,000, 1:1,000 or 1:500 parts DDT in water at a rate of about 13 pints per 1 yard. The manure was left uncovered after treatment except on one occasion when rain threatened and 3-6 days later 600-1,200 puparia collected from it were placed in groups of 100 in tubes containing a little damp earth and the flies that emerged were counted. The results showed that the percentages of normal, semi-normal and abnormal adults and of puparia from which no emergence occurred were 25.46, 7.23, 1.23 and 55.07 for DDT at 1:1,000, 1:1,000, 1:500 and 93.7 for DDT at 1:1,000 and 11.16, 0.16, 1.44 and 87 in series and 22.5, 16.8, 15 and 45.7 in another for DDT at 1:500. Many of the pupae from which no emergence occurred were abnormal in appearance and dead larvae in all instars were numerous in the treated manure in the trough.

DE MEILLON B, THORP J M. & HARDY F. An Apparatus for the Rapid Screening of Drugs for possible use in Chemotherapeutic Control of Ectoparasites and some Results obtained with it. *South African J Med Sci* 1943, June v 13 No. 3 115-19 1 fig. [14 refs.]

The apparatus consists of a metal slide with a circular depression (about one inch in diameter) which holds about one ml. of blood. Blood is withdrawn from an animal and defibrinated by stirring, before it is added to the cavity. One advantage of the small quantity of blood is that there is little tendency for cells and serum to separate which is important since either serum or cells alone are toxic for some blood-sucking insects (e.g. bed bugs). The metal slide is kept at blood heat on a warm stage and the feeding tube closed with a membrane is placed on it so that it just fits into the blood filled cavity (and displaces a little blood round the rim, which draws and forms a seal).

The feeding tube and membrane are made as follows. A mouse is killed and the whole body is treated with a depilatory (50 per cent barium sulphide, 50 per cent chalk). After thorough washing, the skin is removed and washed in running water for an hour or so, dried on blotting paper and stretched over the mouth of the tube where it is fixed by a rubber band. After use the skin is washed in water *in situ*, dried and stored in a cupboard. It can be used again up to a week after preparation. The feeding tube should not be more than two inches long.

For testing possible insecticidal compounds the samples are added to the blood and ground with it in an agate mortar. Or they can be added in aqueous solution provided that not more than 10 per cent. water is added to the blood.

The compounds tested by the authors follow the work of H. V. D. (et al) [this Bulletin 1943, v 45 815] who showed that the indandione series were promising as chemotherapeutic agents against blood sucking arthropods. This fact is confirmed. Particularly promising are the substances related to vitamin K, i.e. anti-haemorrhagic agents the calcium and sodium salt of 2-methyl-1,4-naphthahydroquinone diphosphate (Synkafit).

J. R. D. 1944

WILSON S. G. A Method of assessing the Acaricidal Properties of DDT and "Gammaxane" Preparations in Field Trials. *Bull Entom Res* 1943 Aug. v 38 Pt. 2, 239-76 5 figs.

Cattle in the neighbourhood of Entebbe, Uganda are liable to be infested with a variety of tick species which characteristically attach at different parts of the body. Some preliminary indications of the chosen foci of several ticks

are given in a sketch. For the purpose of insecticidal tests, it would be difficult to make complete counts, therefore results were judged on the counts of *Rhipicephalus appendiculatus* attached on the ears and *Amblyomma variegatum* on the udder and flanks of cattle.

For control purposes, DDT and gamma BHC have many advantages over arsenic. Some trials of these preparations were made with a DDT emulsion and a gamma BHC aqueous suspension (prepared from the dispersible powder P530). Preliminary field trials showed that both 2.5 per cent DDT or 0.325 to 0.65 gamma BHC gave a fairly good kill of the ticks, but very little protective action beyond four days. The addition of coumarone resin to the DDT emulsion did not improve its residual action. At the suggested rates, it would be necessary to treat cattle weekly to obtain control.

Treatment was easily achieved by spraying the cattle's ears with a "Kent" type sprayer, while they walked through a bath of insecticide which treated the udder and flanks.

LAW, S. G. A Biological Test for assessing the Acaricidal Properties of DDT and "Gammexane" Preparations. *Bull. Entom. Res.* 1948, Aug., v 39, Pt 2, 277-9, 1 fig.

For each test an open-ended tube, 10 cm. long by 2 cm. in diameter is used. It is lined with a small roll of filter paper which is moistened with 0.5 ml. of the insecticide liquid under test. The ends of the tube are sealed by caps formed of filter paper moistened with the insecticide in the same way and bound in position with gummed paper while still moist.

The ticks (either laboratory bred or freshly collected) are placed on a square of filter paper and swabbed with the test solution. About 10 are used for each test. They are then placed in the prepared tube by removing and then replacing one of the paper caps. The tube is left horizontal and the filter paper caps, etc., dry in 3-6 hours. Mortalities of ticks are determined after 6, 24, 48 and 72 hours.

It is claimed that the method reproduces the conditions of practical dipping of infested animals, in which the ticks experience initial soaking in insecticide, followed by exposure to a moist surface which gradually dries.

PLACKETT, R. L. & HEWLETT, P. S. Statistical Aspects of the Independent Joint Action of Poisons, particularly Insecticides. I. The Toxicity of a Mixture of Poisons. *Ann. Applied Biol.* 1948, Sept., v 35, No 3, 347-58, 5 figs. [14 refs.]

RAMALHO, A. C. R. & RABELLO, E. X. Sobre uma nova fórmula de corante para material entomológico. [A New Staining Formula for Entomological Material]. *Gaz. Clínica*, S. Paulo, 1947, Nov.-Dec., v 45, Nos 11/12, 169-70.

The authors give the formula of a stain which they have found to be suitable and constant for small insects or for minute parts of small insects such as genitalia, mouthparts, etc., for microscopical examination. It is made up of one gramme of fuchsin and 1 gramme of eosin dissolved in 100 cc. of 80 per cent alcohol to which is added 100 cc. of 10 per cent acetic acid. The mixture must be filtered before use.

After the insect or part has been softened and cleared in warm 10 per cent caustic potash, it is put straight into the stain and gently warmed for a minute or so. The rest of the procedure is as usual through creosote to Canada balsam for mounting.

BOOK REVIEWS

GRADWOHL, R. B. II [M.D. D.Sc., F.R.S.T.M. & H. (London) etc., *Clinical Laboratory Methods and Diagnosis. A Textbook on Laboratory Procedures with their Interpretation. Vol. I. 4th Edition. pp. xbi+1294 41 coloured pls. 362 text figs., 4 charts & 5 graphs. 1948. St. Louis: The C. V. Mosby Company. [3 vols. \$40]*

This the fourth edition of a book which has been generally acknowledged as a standard work has proved to be a stupendous undertaking. From comparatively modest beginnings in 1905 it has blossomed out into three bulky volumes of which the first two are devoted to laboratory procedures and the third to parasitology. Of the three before us this first undoubtedly contains the most indispensable information and is also the most bulky. It is almost impossible within the space of a review to give an adequate idea of the mass of detail which this book contains, most of which is essential to the modern laboratory worker. There are nine chapters. The first is devoted to general considerations, such as the microscope, photomicrography, the analytical balance, metric weights and measures, general facts on solutions and an explanation of the hydrogen ion concentrations. Chapter II deals mainly with urine analysis. Among other methods are general directions for collecting specimens, detection of sugar, albumin and proteoses, determination of drugs in urine, microscopic examination, special urine chemistry, cystoscopic urinalysis and estimation of kidney functions.

As the author announces in the preface, one of the fundamental subjects in modern haematology so that the next three chapters, III to V, are occupied with the most complete and up-to-date account of this important specialty grouped under the headings of blood chemistry, haematology, blood grouping and transfusion. This is undoubtedly the high-water mark of the book and the treatment of this huge subject is almost without a rival. Here we find directions for methods of procuring and handling blood for chemical examination, clinical colorimetry, the technique of blood chemistry, blood sugar estimation, glucose tolerance test, total non-protein nitrogen, interpretation of blood changes in nephritis, liver function tests, cholesterol, calcium, inorganic phosphorus, acidosis, blood ketones, sulphonamide drugs and estimation of blood thiocyanates. Haematology proper deals with the origin of blood cells, the physiology of haematopoietic organs, normal composition of the blood, description of stained cells, bone marrow studies, special staining methods, tests for coagulation of blood, relationship of the liver to blood disorder and diseases of the reticulo-endothelial system, blood picture in various infectious diseases and haematology of infants and children.

Blood groups and transfusions demand a knowledge of the technique of blood grouping, agglutininogen Rh in human blood, whole blood transfusion and prevention of haemolytic reaction, blood plasma, bone marrow infusion, protein metabolism and parenteral protein hydrolysate, blood groups and heredity.

Chapter VI deals exhaustively with gastric analysis, test meal examination, microscopic examination and the conclusion to be drawn and similarly the technique of estimation of duodenal contents.

Chapter VII is devoted to the examination of puncture fluid, cellular structure of effusion, aspiration biopsies and cerebrospinal fluid.

In Chapter VIII the faeces are given general consideration and the account follows accepted lines.

In Chapter IX special tests are described, among directions such as determination of cystine in fingernails, laboratory test for pregnancy, arterial

smears, suction curettage, hypersensitiveness, protein sensitization, mycological diagnosis, semen appraisal, deficiency diseases and special tests in connexion with examination of food contamination

The whole book appears to be meticulously compiled and the descriptions are particularly clear and accurate. A feature which will commend itself is the full documentation in the form of footnotes.

The volume is printed on art paper, the type is clear and all the figures, photographic and otherwise, are beautifully reproduced and this especially applies to the coloured plates of blood pictures and bone marrow smears. Laboratory workers the world over will be grateful to Dr Gradwohl in having completed such an outstanding compilation.

P Manson-Bahr

GRADWOHL, R B H [M D, D Sc, F R S T M & H (London), etc.] **Clinical Laboratory Methods and Diagnosis. A Textbook on Laboratory Procedures with their Interpretation. Vol II. 4th Edition.** pp 1297-2284 + 127 pp of Index to Vols I & II, 328 text figs & 10 coloured pls. 1948. St Louis. The C V Mosby Company. [3 vols \$40]

This is the second volume of the fourth edition of what has become a much valued book of reference on a large variety of technical procedures, though throughout it has managed to preserve its human values without degenerating, as it might so easily have done, into a mere encyclopaedia. The main topics are grouped under the headings of Bacteriologic Application to Clinical Diagnoses, Serology, Postmortem Examinations, Tissue Cutting and Staining, Preparation of Museum Specimens, Toxicological Technique, Detection of Crime by Laboratory Methods, Basal Metabolism, Electrocardiography, Museum Supplies, Equipment and Reagents for Pathological Laboratories. This surely constitutes a motley heterogeneous collection, but the reader must not imagine because it is so, that each section does not provide an up-to-date authoritative account of each subject, so that the book has become an indispensable adjunct of every pathological and clinical laboratory.

We can point out, for instance, the value of a list of certified stains prepared by the Biological Stain Commission and this includes the methods of application. A very useful plate (XLII) illustrates the tints produced by adding phenolsulphonaphthalein (phenol red) to a series of phosphate solutions of H ion concentrations indicated in each case by pH.

Some 43 pages are devoted to the preparation of various specialized media and some 20 to culture methods. The classification and identification of pathogenic organisms are gone into at great length and in this respect the *Salmonella* group is given special preference in a manner hardly to be found elsewhere, and a table (XCVI) epitomizes the characteristics of no less than 113 members of this group. It is surprising to find that the dysentery bacilli in contrast receive so little attention. Those spirochaetes which are referred to under the generic title of *Borrelia* are dealt with more extensively in Vol III but the genera *Treponema* and *Leptospira* receive their due.

In the section on tuberculosis, the simplification of fluorescence microscopy as devised by Graham is given in detail. The bacteriology of milk, testing of disinfectants, the vexed question of bacteriophage in diagnosis and therapy are each considered in the light of modern knowledge and the reader will also find a fairly complete account of rickettsias and virus diseases and the classification of the latter is compressed in table form (CXIX). Rabies also receives considerable space and a resume is given of the Pasteur treatment of this fell disease. The section on serology occupies more than 100 pages, the greater part being taken up by various modifications of the Wassermann and Kahn tests.

It is possibly more detailed than in any other publication and also includes the technique for the complement fixation test for amoebiasis.

Chapter XII which describes postmortem examination is well illustrated with elaborate and expensive apparatus such as is seldom available to pathologists in this country.

Chapter XIII on tissue cutting and staining follows on well tried lines and describes the technique of frozen section according to the method of Krause, whilst great importance is paid to the selective cytology of Ayre for obtaining biopsy material from the cervix uteri. T. V. urological methods and the detection of crime occupy a niche of their own and demand such specialized apparatus and technique as to be outside the scope of the ordinary medical reader. They include the sensational polygraph or "lie detector". In basal metabolism we find ourselves in a new world and these investigations embrace many elaborate methods to which perhaps too little attention has been devoted on this side of the Atlantic. It might be thought that electrocardiography was such a wide subject that it should embrace a whole volume to itself but it is here disposed of in 50 pages so that we must agree with the conclusion that this chapter is intended to give the reader only an introduction to the subject even if it unfortunately conveys the impression that a normal electrocardiogram does not always exclude the presence of organic heart disease.

Chapter XIV which consists of a list of the minimum requirement and supplies, equipment and reagents to furnish pathological laboratories should impress the tyro with the truly herculean task which lies before him.

It is hardly necessary to state that this publication is beautifully produced and printed on the best art paper that the illustrations are all that could be desired and that the binding is substantial as well as attractive. Such are the advantages of the absence of austerity in medical books to which the great of the times have accustomed us in Great Britain.

Search for misprints or inaccuracies has been in vain but we would like to draw the attention of the able reader of Chapter V to the Americanization of such a familiar name as that of Sabouraud.

P. V. von Dake

GRADWOLD, R. B. H. (M.D. D.Sc. F.R.S.M. & H. (London) etc. & ROSSI, Pedro (Director, Institute of Tropical Medicine, Havana University etc. Clinical Laboratory Methods and Diagnosis, Vol. III, Parasitology and Tropical Medicine, 4th Edition, pp. viii+864 (201 vi fig. 17 coloured pls. 1918, St. Louis: The C. V. Mosby Company) 3 ls. \$40

This third volume is undoubtedly a book which will arouse considerable interest and no doubt give rise to some measure of comment spreading. It has done like a new constellation in the southern hemisphere among a full account of tropical parasitology. In some respects it has succeeded in doing so in others it has failed. Quite naturally there is laid upon the not inconsiderable achievements of the Cuban and South American schools—and in the book: none the worse for that.

The work is illuminated throughout by essays upon the underlying principles of helminthology and protozoology. Thus we find a history of these respective sciences and an enunciation of the nomenclature of parasitism, reaction of the organism to infection and methods of diagnosis. The subject of medical protozoology is handled on biological lines and the amoebae *E. histolytica* in particular are minutely described and handsomely illustrated but it must be confessed that the clinical section, not so fortunate in treatment in particular, an optimistic attitude is adopted. A large series of drugs is advocated special prominence being given to the product of the Laboratory Kala. The intestinal flagellates which are really of minor importance are given perhaps

undue prominence. In a work on tropical medicine it might have been expected that malaria would occupy a position of prime importance, but in this expectation we are disappointed and find an inadequate and somewhat fallacious account crammed into some 27 pages. A coloured plate (Pl IV) conveys what is now known to be an incorrect idea of the life history of the main species of human *Plasmodium*. No allusion is made to the exoerythrocytic cycle, but Schaudinn's original figure of the penetration of the sporozoite into the erythrocyte is reproduced (Fig 47) as well as a purely imaginary diagram (Fig 55) copied from Brumpt and Neveu-Lemaire showing a hypothetical tissue stage in the capillary endothelium in the case of *P falciparum*. It conveys the impression that a study has not been made of the vast literature of this subject and imparts the idea that *P falciparum* is the longest-living malaria parasite in the human body, through a misprint on p 228 of this species for *P malariae*.

In the same vein it is permissible to annadvert upon the section on human and animal trypanosomes, which enormous subject is dismissed in 13 pages, while the almost equally important subject of the leishmaniases is vouchsafed only two. In contrast to this meagre appropriation, the section on helminthology, which is mainly based upon the observations of the junior author, is a massive affair occupying no less than 523 pages. It is illustrated by magnificent photographs mainly by Kouri, and also by fine line diagrams, so that it is questionable whether anything of its kind exists in any other publication. Some may consider it pretentious, others, rather unbalanced because considerable space is devoted to the rarer or accidental helminthic human infections. It is questionable, too, whether so much importance should be attached to infections such as trichuriasis and to the practice of crediting the whipworm with pathogenic properties on rather slender ground. To the clinician this constitutes rather a dangerous practice. In this connexion there is a remarkable plate (Fig 65) depicting the hatching of the larval trichurids from the egg. No mention is made of the parasitic male of *Strongyloides stercoralis*. Again, undue space of 3 pages is given to *Heterodera marioni* (*radicicola*), the egg of which is merely fortuitous in the faeces.

To the reviewer, filariasis is naturally rather a hallowed subject and possibly on that account he is apt to be rather sensitive about the history of this important nematode, but in the case of the non-periodic form, referred to as

"Filariasis in the Samoan area", the story is positively misleading, while the photograph of that handsome mosquito, *Aedes scutellaris* (Fig 163), is badly fogged. The crowning achievement is undoubtedly to be found in the description of the Cestoda which occupies alone 72 pages. Here great attention is paid to the rarer forms which are accidental in man. Thus twelve illustrations and as many pages are devoted to *Inermicapsifer cubensis* which has hitherto not been recorded except from Cuba, and the account is based upon specimens derived from some 75 cases.

Raillietina quitensis was described by Luis A LEÓN in 1938, in Ecuador, where some human infections have been recorded, it is another rare species but no attempt has been made to unravel the obscure life history of either of these two cestodes or to discover their normal hosts. In a similar vein, great attention has been paid to *Hymenolepis* which appears to be a common intestinal parasite in Cuba. In direct contrast to this prolixity that section devoted to diseases caused by spirochaetes, viruses, bacteria and also those due to arthropoda constitutes an absolute anticlimax, and this vast amount of information which should require a volume on its own is dismissed in 65 pages.

In this review we have endeavoured to be fair in appraising the virtues of a notable production and at the same time pointing out some imperfections for the attention of the conscientious and diligent authors of this work on

parasitology. It is hardly necessary to add that the general finish and format of this book could hardly be bettered.

P. Manson-Bahr

DEBOIS, Albert (Directeur de l'Institut de Médecine tropicale d'Anvers etc. & VAN DEN BERGHE Louis [Directeur de l'Institut pour la Recherche Scientifique en Afrique Centrale etc.] *Les maladies des pays chauds. Symptômes, diagnostic et traitement.* (The Diseases of Hot Countries) pp. xvi+489 100 figs. & 91 graphs. 1947 Paris: Masson et Co. Editeurs, 120 Boulevard Saint-Germain.

This latest addition to the rapidly growing family of small books on tropical diseases deserves a hearty welcome from every French-reading medical man in the tropics. The authors state that their aim has been to provide in concise form reliable information with regard to the diagnosis and treatment of the chief diseases of hot countries. It can be said at once that they have achieved their object in a very successful manner. The book is well written and attractively produced. The subject matter has been carefully chosen and the most exacting critic will find it difficult to discover errors in the text. The illustrations are excellent—they consist of 100 reproductions of photographs nearly all of which are original.

Diseases which are not appreciably more common in hot than in cool countries have been excluded—for example the brucelloses and spirochaetosis—but fortunately the authors have not adhered slavishly to their principle. Including exclusively diseases of hot climates otherwise they could not have admitted the helpful description of louse-borne typhus—a disease which flourishes specially in cold weather.

The classification—or rather the order of arrangement—of the diseases is based on their clinical features and on the regions of the body that are affected, not on the nature of the causative agents. This classification will doubtless arouse criticism in some quarters but it can be defended on the grounds of convenience and helpfulness to the doctor.

The scope of the book can best be shown by a summary of the content: the figures in brackets show the approximate number of pages allotted to the various subjects.

I. *Geographical Distribution* (7). II. *Climatology* (12), including five pages on diseases caused in heat. III. *Commonest Diseases in the Tropics* (24). IV. *General Infections* (173) including sleeping sickness (36) Chaga disease (9) visceral leishmaniasis (10) malaria (48) blackwater fever (10) lapping fevers (11) rickettsial diseases (22) plague (10) yellow fever (10) dengue (3) and three days fever (3). V. *Intestinal Diseases* (78) including bacillary dysentery (8) amoebic dysentery and liver abscess (17) cholera (4) schistosomiasis (18) hookworm disease (9) and other helminthic diseases of the intestines (14). VI. *Skin Diseases* (92) including leprosy (22) mycoses (10) yaws (9) and filarial diseases (38). VII. *Injuries caused by Animals and Plants* (9) including snake-bite (4). VIII. *Flies and Mosquitoes* (20).

Five pages are given up to a useful description of certain modern drugs but many readers will grudge the allotment of eight pages to a series of diagrams showing the chemical structure of some important substances. The appendix of 16 pages dealing with some common and important laboratory methods will be very helpful to medical men working in isolated outposts.

The authors willingly admit that as professors at the *Belgian Institut de Médecine tropicale d'Anvers* their personal experience and special knowledge are related chiefly to African diseases but they claim that they have maintained a cosmopolitan outlook on the subject. On the whole this claim is justified.

though the allotment of only four pages each to cholera and snake-bite would be considered inadequate for workers in countries in which these diseases are important

The authors pay a graceful tribute to "*L'Excellent Tropical Diseases Bulletin*" which readers are advised to consult for detailed and up-to-date information

An English version of the book is said to be in the course of preparation

In one respect the book has been fortunate in the time of its appearance, important advances in connexion with treatment have been exceptionally numerous during the past two or three years, and all but the very latest have been incorporated by the authors

John W D Megaw

ROCKEFELLER FOUNDATION INTERNATIONAL HEALTH DIVISION Annual Report 1947 pp 1+209, 13 figs on 6 pls New York 49 West 49th Street

To read the Annual Report of the International Health Division of the Rockefeller Foundation is to take a tour from Chile to China, to learn much about a mixture of diseases from Bwamba fever (undoubtedly the most common virus disease of man in West Africa, where there is also evidence of Japanese B encephalitis) to diphtheria, and to see the form of progress in subjects varying from Health Insurance to the training of Sanitary Engineers. That diverse mixture is the measure of the influence of the International Health Division, for none of the subjects is taken up lightly or without altering our general conception of the subject studied

As is common, major parts of the report are devoted to yellow fever and malaria, the first includes an interesting account of serological studies of the virus, a statement of the epidemiology of jungle yellow fever in East Africa which most people will find illuminating, and much incidental matter of which the most intriguing is the application of nuclear physics to tracing the movements of mosquitoes, tagged in the larval stage by exposure to radio-phosphorus or radio strontium. The section on malaria includes notes on the physiology of the parasite and accounts of work in several countries, of which the most interesting is perhaps the story of the effort to eradicate from Sardinia the anophelines which carry malaria. Influenza also receives considerable notice with an account of the relationship of the two viruses, their epidemiology, efforts to produce active immunization and unsuccessful ones to produce clinical cure

There is a short but critical and thoughtful article on Medical Care. A writer who has surveyed trends in twelve countries emphasizes the increasing recognition of the importance of nutrition, housing, recreation, education and social security in the general field of medicine, and the necessity for Governmental interference if they are to receive proper attention, including the removal of economic barriers to adequate medical service. The defects in planning which he considers to be common are failure (except in Australia) to consider the types of staff required and the training needed to put the plans into practice; planning for the cure of rather than the prevention of sickness, and inadequate provision for mental and rehabilitation services and the care of chronic sick. As minor defects he lists lack of appreciation of advances in other countries, and the disregard except in Canada and U.S.A., of the need for auxiliary medical staff. The pleasure of reading the report is only mildly marred by disappointment that he was kept in ignorance of the fact that there is standardized training controlled by a national organization for some auxiliaries in Britain

A constructive proposal the R part advocates a revolutionary change or re-orientation in medical education: the provision of Health Centres, where a association with teaching hospital and the extension by medical school of their facilities to include the care of the health of a designated community of some 100,000 to 200,000 population.

There are many other subjects which could be mentioned with much appropriateness in a review. It is a record of one year of highly constructive work.

C. Macdonald

Smart, John (M.A. D.Sc. Dept. of Zoology, University of Cambridge).
A Handbook for the Identification of Insects of Medical Importance. With Chapters on Fleas by Dr. Karl Jordan F.R.S. and on Arachnids by R. J. Whittick B.Sc. 2nd Edition. pp. xi+293 13 pl. (3 coloured) & 174 fig. 1948. June. London: British Museum (Natural History). 20s.

The first edition of Dr. Smart's book was published in 1943 (see this Bulletin 1944: 41-329) and the call within four years of publication for a second impression and a second edition proves the continued need for an authoritative but not too lengthy guide to arthropods of medical importance. The present edition has been increased by some 30 pages. It contains a number of new illustrations: the latter include an original drawing of *IT* (not *IT* draws) to replace the previous and much less satisfactory illustration borrowed from Castellani and Chalmers. The section on *Glyptotendipes* has been lengthened to include fresh material concerning the geographical distribution and vegetative associations of different species of larvae. Dr. Kenneth M. Usher has revised the chapter on Arachnids and the life-cycle of *Sarcoptes scabiei* is now described as similar to that of *Notoedres* in that all stages (except mature female) may inhabit small, almost invisible moulting pocket in the most superficial layers of the stratum corneum. The chapter on anophelines contains a notable *Plasmodium* vector ranking in order of importance contributed by Mr. H. S. Leeson. The most comprehensive alteration occurs in the section on *Beetles*, which Dr. Karl Jordan has re-written and extended by some 11 pages. Finally, a very welcome improvement is the much more comprehensive index added at the time of the second printing.

The second edition did the first contain descriptions of such genera as *Gasterophilus*, *Hypoderma*, *Melophagus* and *Hemaphysalis*. The inclusion of insects so seldom injurious to man in a book otherwise solely concerned with medical entomology seems unnecessary.

The first edition was published at 15/-; the second edition maintains the high standard of production of its predecessor and is printed on a more substantial paper at the remarkably low price of 20s. R. M. Gordon

SUMMARY OF RECENT ABSTRACTS*

III MALARIA

[Continued from p 204]

Treatment

General—The Expert Committee on Malaria of the World Health Organization has issued reports of its first and second sessions (pp 389, 948). The first sums up much modern work on antimalaria drugs and DDT. In the second a particularly important feature is a statement of the dosages advised for the drugs in common use (which are set out in detail in the abstract).

A series of tests of potential antimalarial drugs was carried out on 500 prisoners in the United States, most of the drugs were members of the 8-aminoquinoline group. ALVING *et al* (p 951) explain that the Chesson strain of *P vivax* (with high relapse rate) was used, with *A quadrimaculatus*. In the first paper (JONES *et al*, p 951) it is shown that pamaquin, pentaquine and two other drugs may act as true prophylactics, but that they did not protect all subjects, they are, however, too toxic for this purpose. Another compound, SN-10,275 is also too toxic for use (PULLMAN *et al*, p 952). Serious reactions occurred with pentaquine at a dose of 120 mgm of the base each day, along with quinine (CRAIGE *et al*, p 953). In doses of 30 or 60 mgm of base daily, with quinine, however, the effect on fever and on the relapse rate was very good, even in heavy infections. Pentaquine should be administered only under close medical supervision, and the daily dose should not exceed 60 mgm, it should not be used for prolonged suppression (ALVING *et al*, p 953).

ALVING *et al* (p 954) found that the curative properties of pamaquin are shared by several analogues, but no definite conclusions can be drawn as to the specific molecular configuration required in a curative drug. Régimes which produce a high percentage of cures tend to prolong latent periods in those they fail to cure.

Under the conditions of the experiment, chloroquine proved superior to quinine and mepacrine, the dosage was 2.0 gm in one week (PULLMAN *et al*, p 955). It is safe if given in recommended doses, and ALVING *et al* (p 956) suggest 1.5 gm of the base [2.5 gm of the diphosphate] in three days for the

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1948 v 45. References to the abstracts are given under the names of the authors quoted, and the pages on which the abstracts are printed.

cure of attacks of *P. vivax* or *P. falciparum* malaria, and 0.3 gm. (0.3 gm. diphosphate) each week for suppression.

Results reported by JONES *et al.* (p. 835) indicated that paludrine was not as effective as mepacrine or chloroquine in terminating acute attacks, but that it was valuable and had only negligible toxic effects. It had no synergic action with either quinine or pamaquine.

In a second series of studies on chemotherapy in human malaria, SWANSON *et al.* (p. 836) worked with the McCoy strain of *P. vivax*, which is more susceptible than the Chesson strain to quinine. They show that blood forms derived from blood inoculation, and those from sporozoite infection are equally susceptible to quinine. The effect of quinine is correlated with its concentration in plasma, but is independent of the degree of parasitaemia. Similar results were observed (EARLE *et al.*, p. 857) when *P. falciparum* infections were induced by infection of infected blood, and therapeutic response to quinine was correlated with duration of treatment and with plasma concentration. There was some difference in the response of another strain of *P. falciparum*. The physiological disposition and antimalarial activity of the cinchona alkaloids were studied by TAGGART *et al.* (p. 958) who showed that plasma concentrations after identical doses varied widely in different subjects, and between the different alkaloids. EARLE *et al.* (p. 959) discuss the metabolism of cinchonine.

The antimalarial action of quinaquine (mepacrine) in *P. vivax* and *P. falciparum* infections was studied by TAGGART *et al.* (p. 960) and of chloroquine and other aminoquinolines, and of pamaquin by BRILLNER *et al.* (pp. 961-963) with results similar to those of other investigations, while ZUCKER *et al.* (p. 962) report on the physiological disposition of pamaquin, and EARLE *et al.* (p. 962) on its effect on human red blood cells. Details of these findings cannot satisfactorily be further abstracted.

EARLE *et al.* (p. 963) reached the conclusion that paludrine is extremely effective against the McCoy strain of *P. vivax* but the Costa strain of *P. falciparum* was more resistant. Paludrine is the most active suppressive agent yet described in *P. vivax* malaria.

ANDREWS and CORRYATZER (p. 396) show that cinchonidine is metabolized more quickly than cinchonidine or quinine in man.

MAIER (p. 971) shows that even in patients with acute dysentery quinine and mepacrine are absorbed normally.

MAIER *et al.* (p. 880) found little difference in the results of treatment of *P. falciparum* malaria with mepacrine (3.6 gm. in 6 days) and with quinine (210 grains in 6 days). Nervous symptoms were observed in a few patients on mepacrine.

JAILER *et al.* (p. 575) refer to the fact that excretion of quinine is increased if the urine is acid, and show that the same is true of mepacrine, chloroquine and pantoquine. Administration of ammonium chloride to render the urine acid, may therefore be useful if there are symptoms of drug toxicity.

LEVES (p. 33) reports on the experience of the Army malaria research team in relation to treatment of *P. vivax* malaria with quinine, mepacrine, pamaquin and paludrine. He discusses their rapidity of action, the stages of the parasites on which they act, and their effects on relapses. For details the original book should be consulted.

MOORE (p. 1053) has summed up recent developments in the treatment of *P. vivax* infections. Paludrine and chloroquine are about equally effective in suppression. For the acute attacks quinine (or paludrine) and pamaquin given concurrently are very satisfactory but quinine and pantoquine (which is rather less toxic than pamaquin) together are probably better in reducing the relapse rate.

WINCKEL (pp 144, 145) discusses the continuing value of quinine in malaria, and suggests that the hydrochloride should be used in place of the too acid bishydrochloride for intramuscular injection, thus reducing the amount of necrosis and the chance of infection.

WINCKEL (p 303) demonstrates that there is no good reason to think that the use of quinine in pregnancy leads to congenital defects of the ear or eye of the foetus.

MAMOU (p 237) reports a case of intolerance to quinine, two intramuscular injections of 1 gm gave rise to haemorrhagic purpura.

There is, in various animal tissues, especially the liver, an enzyme which acts on quinine, converting it to the 2-hydroxy derivative CHEN (p 397) shows that both mepacrine and pamaquin inhibit the conversion of quinine, probably by acting on the enzyme.

COATNEY *et al* (p 680) show that quinine sulphate in doses of 0.5 gm daily for 4 days before infection with *P. vivax* and for 21 days thereafter suppressed the early primary attack, but that the attack occurred after an incubation period of 260-332 days. Doses of 0.25 gm for the same period usually failed, and larger doses not continued beyond 6 days after infection also failed.

STRAHAN (p 574) describes the treatment, based on quinine, given to the malnourished prisoners of war near Singapore during the Japanese occupation. For very heavy infections quinine was given by intravenous drip regardless of the clinical condition, at the rate of 2 gm (in 3-4 litres) in 24 hours, and continued, if necessary, for several days. The rate of flow was 30-40 drops per minute.

FIELD *et al* (p 577) gave neoarsphenamine, in addition to quinine, to patients with *P. vivax* malaria in internment camps near Singapore, but did not observe any benefit from the neoarsphenamine.

CHEN and GEILING (p 490) show that quinine and plasmoquine show a synergistic action as regards toxicity and therapeutic action, and the same is true of quinine and pentaquine. Quinine and atebryn, and atebryn and plasmoquine, act independently.

SPICKNALL and TERRY (p 753) report good results from combined quinine-plasmoquine or quinine-pentaquine treatment in relapsing *P. vivax* malaria.

Mepacrine, etc—MACHELLA *et al* (p 304) have shown that intravenous mepacrine in dilute solution (1 in 1,000 in saline) is well tolerated up to a dose of 1.0 gm, but should be given by the drip method over a period of 3-4 hours.

PARMER (p 1058) shows that there is a considerable amount of mepacrine in the bone marrow of rabbits on the 4th day after administration, although the blood is almost free. There is, however, no apparently direct relationship between mepacrine and aplastic anaemia, which is probably a matter of idiosyncrasy.

JAILER *et al* (p 681) have investigated the effect of acidosis and anoxia on concentrations of mepacrine and chloroquine in blood. CO₂ acidosis increases the proportion found in plasma and red cells as against the proportion in the tissues, but anoxia has no such action.

SINGH (p 1059) reports 83 cases of atypical lichen planus in patients who had taken mepacrine, and describes the condition, in most cases the onset was acute. He did not see this disease in persons who were not taking suppressive mepacrine, and the severity seemed to be related to the amount stored in the skin.

PERR (p 398) discusses mepacrine psychoses, describing 23 cases seen in the Middle East. Other factors than mepacrine may have been important—emotional stress, battle stress or alcoholism. Most of the cases arose after therapeutic doses had been given (3.4 gm in 6 days). The most frequent

symptoms were schizophrenic and manic in type, with incoherence and a change in behaviour in the early stages.

Two cases of fugue after administration of mepacrine are recorded by MACDONALD (p. 237).

HOEBLER (p. 238) reports that a number of toxic nervous symptoms occurred in a group of volunteers (not in a malarial region) who took either the usual suppressive doses of mepacrine for two weeks or rather high therapeutic doses for a few days. This is not a usual finding.

Four cases of mepacrine psychosis are described by PARAJOTY (p. 237).

EL-DIK NOUR EL DIK (p. 1060) reports a few cases of mepacrine psychosis. Instead of giving the acridine drug Italcina in daily doses of 0.3 gm. for 5-7 days, BUONOMINI and MOTTA DIANA (p. 399) used 0.5-0.8 gm. each day for 4 days for both *P. vivax* and *P. falciparum* infections, with advantage.

Paludrine—A general review of paludrine was published in 1947 by FIELD (p. 861).

GREEN and AVDEYEV (p. 491) describe the general pharmacology of paludrine. MULLICK and GUPTA (p. 755) have given paludrine intravenously without serious toxic symptoms.

Paludrine acts on the dividing nucleus of early schizonts of *P. vivax*. Gametocytes of *P. vivax* or *P. falciparum* if enough of the drug is present in the blood taken up by the mosquito, fail to develop beyond the stage of encystment and MACKERRAS and ESCOFFER (p. 305) have shown that for 10 days after treatment is stopped there may be enough paludrine to affect development, but not after the 12th day.

MARSHALL (p. 49) suggests that paludrine probably acts by inhibiting the oxidation processes of the malarial parasite and quotes the evidence on which he bases his opinion.

SHUTZ and MANNON (p. 578) have examined the action of paludrine on the gametocytes of *P. falciparum* and show that mosquitoes fed upon a patient up to 7 days after cessation of paludrine failed to become infected. This confirms earlier work by FAIRLEY and his team.

In India 6 trials of paludrine were conducted by independent workers whose reports are reviewed together (p. 880). A comment on the whole series is offered by ARKIDIS (p. 882) who shows that the disease was microscopically diagnosed in all cases. 1,283 *P. falciparum*, 491 *P. vivax*, 88 *P. malariae* and 59 mixed. Acute *P. falciparum* infections responded better than *P. vivax* and the response of *P. malariae* was often delayed. Paludrine is as effective against Indian as against other strains, and a single dose of 0.3 gm. usually suffices for clinical cure. This dose could be used in the hospital and dispensaries of India and relapses could be treated as they arise or 0.1 gm. could be taken once or twice each week.

In a trial of paludrine in cases of subtertian and benign tertian malaria in India ARKIDIS *et al.* (p. 233) found that a single dose of 300 mgm. was enough for a clinical cure of an attack, and that there was no advantage in repeating the dose for several days or in giving mepacrine.

DE and DUTTA (p. 34) have treated a small number of patients with paludrine and report favourably on it. Similar studies are reported by CHAUDHURI and RAI CHAUDHURI (p. 35) and by PARKER and BOGHIANI (p. 76). In these three papers both *P. vivax* and *P. falciparum* cases are recorded, and various regimens were used.

In India GHOSH and GHOSH (p. 147) also report favourably on paludrine.

VISWANATHAN and BAILEY (p. 754) think that paludrine may take its place in the hands of lay village officers for distribution in India. They obtained good results in treatment and suppression with relatively low doses.

Treatment of *P falciparum* malaria in Sardinia with paludrine 0.3 gm daily for 10 days with weekly administration thereafter, was very successful in most cases, though there were some attacks after the first 5 days of treatment. BETTINI (p 861) also reports good results in a few *P vivax* and *P malariae* cases.

WALLS (p 972) thinks that in Sierra Leone paludrine should be taken in a dose of 0.1 gm each day, for effective suppression. He prefers it to other drugs, in suppression or treatment, but in doses greater than have usually been advocated.

Paludrine promptly suppressed symptoms in 89 per cent of patients (mostly with *P vivax*) when 0.2 gm was given in a single dose, and in 97 per cent with 0.4 gm (PINTO, p 400).

WOODRUFF (p 240) found that a single dose of 100 mgm paludrine was enough to control attacks of *P vivax* malaria (mostly relapses) in prisoners of war returned from the Far East, and that 100 mgm taken once each week for 6 months prevented relapse in 18 of the 20 patients for 6 months after the last dose.

ANDREWS *et al* (p 491) found that the relapse rate was about the same after short therapeutic courses of mepacrine and paludrine, but that when a small dose of paludrine was given each week for 6 months after a therapeutic course, the relapse rate was reduced.

SCHNEIDER and MÉCHALI (p 865) in North Africa found only slight differences in effect between paludrine, nivaquine and nivaquine B, but metachloridine gave inconstant results.

Chloroquine, etc—The dose of chloroquine advocated in the *Bull U S Army Med Dept* (p 37) is 5 doses (each 0.5 gm) in 4 days (total 2.5 gm), and for suppression 0.5 gm once each week. Attacks are usually promptly brought under control with this dosage, and in most *P vivax* cases the patients become afebrile and free from parasites within 24–48 hours. There are some mild reactions—pruritus, anorexia, vertigo, etc.

WARTHIN *et al* (p 753) have found that in treatment and suppression of *P vivax* infections chloroquine is as effective as mepacrine, but it is no more effective than mepacrine in preventing relapses.

YOUNG and EYLES (p 680) show that chloroquine clears the blood of *P malariae* (in the doses used) more quickly than mepacrine, quinine or totaquine, it also acts more quickly on *P vivax* than on *P malariae*.

Chloroquine was very effective in cutting short blood-induced *P vivax* malaria when given in doses to a total of 2.5–3 gm in 48 hours (KIERLAND and MCCREIGHT, p 400).

Aralen is another name for chloroquine, KAMAL and ABDEL MESSIH (p 38) gave it in dosages of 2.5 gm in 3 days or 0.5 gm every 4 hours to a total of 2 gm. It was effective in both *P vivax* and *P falciparum* infections.

LUCENA (p 1061) reports favourably on Aralen (which is chloroquine diphosphate) in *P vivax* and *P falciparum* infections in Brazil.

In high doses chloroquine will produce toxic effects in rats, but FITZHUGH *et al* (p 973) show that these doses are higher than would be used in man, the general inference was that it is slightly less toxic than mepacrine for rats.

CRAIGE *et al* (p 868) report two cases in which, during a long course of chloroquine administration, a cutaneous eruption was seen which resembled that occasionally caused by mepacrine.

HALAWANI *et al* (p 681) write that Nivaquine C is a potent antimalarial drug which does not produce toxic symptoms in the doses they propose (1.8 gm in 5 days). It is mainly active against schizonts, their tests were made with *P vivax*.

symptoms were schizophrenic and manic in type with insomnia and a change in behaviour in the early stages.

Two cases of fugue after administration of mepacrine are recorded by MACDONALD (p. 237).

HOODLEY (p. 238) reports that a number of toxic nervous symptoms occurred in a group of volunteers (not in a malaria region) who took either the usual suppressive doses of mepacrine for two weeks or rather high therapeutic doses for a few days. This is not a usual finding.

Four cases of mepacrine psychosis are described by PARAMJOTRY (p. 237).

EL DIX NOUR EL DIX (p. 1067) reports a few cases of mepacrine psychosis.

Instead of giving the acridine drug Italcina in daily doses of 0.7 gm. for 5-7 days, BUONOMINI and MOTTA DIANA (p. 309) used 0.5-0.6 gm. each day for 4 days for both *P. vivax* and *P. falciparum* infections, with advantage.

Paludrine—A general review of paludrine was published in 1947 by FIELD (p. 861).

CHEW and ANDERSON (p. 491) describe the general pharmacology of paludrine.

MULLICK and GUPTA (p. 755) have given paludrine intravenously without serious toxic symptoms.

Paludrine acts on the dividing nucleus of early schizonts of *P. vivax* gametocytes of *P. vivax* or *P. falciparum* if enough of the drug is present in the blood taken up by the mosquito, fail to develop beyond the stage of encystment, and MACKERRAS and ESCOFFER (p. 305) have shown that for 10 days after treatment is stopped there may be enough paludrine to affect development, but not after the 12th day.

MARSHALL (p. 49) suggests that paludrine probably acts by inhibiting the oxidation processes of the malaria parasite and quotes the evidence on which he bases his opinion.

SAUTY and MARYON (p. 578) have examined the action of paludrine on the gametocytes of *P. falciparum* and show that mosquitoes fed upon a patient up to 7 days after cessation of paludrine failed to become infected. This confirms earlier work by FAIRLEY and his team.

In India, 6 trials of paludrine were conducted by independent workers whose reports are reviewed together (p. 862). A comment on the whole series is offered by AFRIDI (p. 862) who shows that the disease was microscopically diagnosed in all cases: 1,285 *P. falciparum*, 481 *P. vivax*, 68 *P. malariae* and 59 mixed. Acute *P. falciparum* infections responded better than *P. vivax* and the response of *P. malariae* was often delayed. Paludrine is effective against Indian as against other strains, and a single dose of 0.3 gm. usually suffices for clinical cure. This dose could be used in the hospital and dispensaries of India, and relapses could be treated as they arise or 0.1 gm. could be taken once or twice each week.

In a trial of paludrine in cases of subtertian and benign tertian malaria in India AFRIDI *et al.* (p. 279) found that a single dose of 300 mgm. was enough for a clinical cure of an attack, and that there was no advantage in repeating the dose for several days, or in giving mepacrine.

DE and DUTTA (p. 34) have treated a small number of patients with paludrine and report favourably on it. Similar studies are reported by CHAUDHURI and RAI CHAUDHURI (p. 35) and by PARKER and BOGHIANI (p. 76). In these three papers both *P. vivax* and *P. falciparum* cases are recorded, and various regimens were used.

In India GHOSH and GHOSH (p. 147) also report favourably on paludrine. VISWANATHAN and BULLY (p. 734) think that paludrine may safely be left in the hands of lay (illage officers for distribution in India: they obtained good results in treatment and suppression with relatively low doses.

GARTRELL and KIKER (p 760) go into the detail of the engineering problems involved. The treatment of the reservoir margins in the Tennessee Valley involves two methods — deepening and filling, diking and dewatering. Dewatering involves the use of pumps and recurring expenditure until the deepening and filling procedure is carried out. The subject is discussed by SIMMS and KIKER (p 1061).

NEWBOLD and COCHRANE (p 307) have devised an automatic siphon for antimalarial work, which has given good results in the West Indies. Details must be sought in the original.

PRATT (p 977) has studied the plant communities of Porto Rico and their relation to the breeding of *A. albimanus* and other species, he discusses the control measures suitable for the various conditions.

GRAY (p 309) has written an account of some of the important mosquitoes of Japan, and of methods of control.

Malaria in Malaya is described in a book by SANDOSHAM (p 1045), who has paid attention to control, but in the period before DDT, and the latest drugs, were available.

Insecticidal methods — MISSIROLI (p 151) gives an account of the campaign undertaken against mosquitoes in Italy, where reliance has been placed on spray-painting of houses with DDT. The figures quoted show striking reduction of mosquitoes, of cases of malaria, and of deaths from malaria and from all causes. The reduction in deaths from all causes is probably a result of the reduction of enteric diseases consequent upon the wide destruction of house flies achieved by DDT.

AZIZ (p 152) gives a detailed account of the work done during 1946 in the *Anopheles*-eradication scheme for Cyprus. Only part of the island was attempted in that year, but the work is to be extended later. DDT in oil was used as a larvicide, and as a residual spray in houses, pyrethrum was also used. The results were satisfactory though complete eradication was not achieved in this first year. The local anophelines are described.

The enormous control scheme undertaken in Greece in 1946, with DDT, is described by VINE (p 492). For hibernating mosquitoes residual spraying was practised with a 5 per cent DDT at 220 mgm per square foot, and for larvicidal work also 5 per cent DDT was used. Aircraft were used for marshes. These applications were made time after time from spring to autumn, and although comprehensive statistical data are not available, the amount of malaria was much less than the expected amount, some 80 per cent of the population at risk having been protected. In addition, flies and sandflies almost disappeared, but bees were little affected after blossom time. The effects of DDT on the 6 000 labourers were negligible.

LIVADAS *et al* (p 758) report on a special investigation they made to assess the results of this programme. They found spleen rates reduced to half the previous figures and parasite rates to one tenth, in unprotected areas the parasite rate had not declined.

LIVADAS (p 758) describes the campaign of the following year, when by house spraying and larvicidal methods, all with DDT, over 4 million people were protected. The mosquitoes were again controlled, but the house flies much less so.

A big programme of house spraying with DDT in the Veneto Provinces of Italy was followed by a great reduction in malaria (SEPULCRI, p 758).

BERBERIAN (p 870) has used 5 per cent DDT in kerosene with success as a residual spray and as a larvicide, in Lebanon where the vectors are *A. sacharovi* and *A. superpictus*.

AFRIDI and BHATIA (p 493) have used DDT as a residual spray near Quetta, India, with success. At a concentration of 25–38 mgm per square foot there

the local troops were good except in Liberia, and they had the desired effect in preventing transport of *A. gambiae*. In comment TREDDER remarks that application of insecticide to aircraft as the sole means of prevention is unreliable. He also points out some inaccuracies in the original paper.

The whole subject of malaria control in West Africa by coastal swamp drainage has been dealt with in a monograph written by GILROY (p. 1043). This should be studied in the original. It is an account of war-time work, and is indispensable to anyone undertaking a similar task.

WALTON (p. 401) in a most important paper has made a close examination of the effects of the extensive and careful larvicide campaign carried on in Freetown Sierra Leone during the war. The number of female *A. gambiae* caught in houses was greatly reduced and on average there was only one infected *A. gambiae* in every 14th room in 18 months. This would mean that only one person in 58 would receive an infective bite in the same period. A figure illustrates the enormous reduction that has taken place in the parasite rate of children during this period, and even among those who became infected the author thinks that most did so when they were outside the controlled area, and gives reasons for his opinion. The number of parasites in the blood of infants increases with age up to ~3 years as does the number infected; thereafter both decline. Comparison with malaria incidence outside the controlled area, and in Freetown as recorded in 1931 shows that great reduction has been effected.

WALTON (p. 1082) has been able to correlate the number of infective bites received each year by children in Freetown, with the parasite rate. He makes the point that reduction of parasite rate to 5 per cent. usually considered a satisfactory result of control, may reduce the children's immunity without any appreciable reduction of the disease. In comment TREDDER considers some possible implications of this view.

MACDONALD (p. 239) has written a long pamphlet on malaria control (for the benefit of laymen and medical men in India (particularly those connected with estates) in which he pays special attention to the new insecticides and drugs now available.

For the control of breeding of Indian anophelines such as in still water in association with various water plants. RAO and RAMAKRISHNA (p. 41) show that manual removal of the plants leads to overgrowth of algae but that this can be avoided by planting the common aquatic herb *Ottelia* (worden). The best prevention is the planting of vegetables on the beds of the tank when they are dry in summer. This seems to render the soil sterile when the water accumulates again.

NAGENDRA (p. 41) writes of the value of dry leaf packing of streams for control of mosquito breeding.

A Committee of engineers and malariologists in India (p. 57) has laid down the principles which should be observed, in road and railway construction so that the risk of malaria may be avoided.

The extensive and carefully planned system of malaria prevention which is now routine in the Tennessee Valley is discussed by BISHOP and HIRSH (p. 759). They point out that many of the engineering features which help to prevent the breeding of anophelines are built in at the stage of construction of the reservoirs. Water level manipulation is now well understood, and together with shore-line maintenance and improvement almost makes the use of larvicide unnecessary. There are sometimes needed however, and DDT has supplanted Paris green; it is also used as residual spray in houses where it gives better protection than routine gauze screening. A full account of malaria control on impounded water has been published by the United States Public Health Service and the Tennessee Valley Authority (p. 822).

GARTRELL and KIKER (p 760) go into the detail of the engineering problems involved. The treatment of the reservoir margins in the Tennessee Valley involves two methods — deepening and filling, diking and dewatering. Dewatering involves the use of pumps and recurring expenditure until the deepening and filling procedure is carried out. The subject is discussed by SIMMS and KIKER (p 1061).

NEWBOLD and COCHRANE (p 307) have devised an automatic siphon for antimalarial work, which has given good results in the West Indies. Details must be sought in the original.

PRATT (p 977) has studied the plant communities of Porto Rico and their relation to the breeding of *A. albimanus* and other species, he discusses the control measures suitable for the various conditions.

GRAY (p 309) has written an account of some of the important mosquitoes of Japan, and of methods of control.

Malaria in Malaya is described in a book by SANDOSHAM (p 1045), who has paid attention to control, but in the period before DDT, and the latest drugs, were available.

Insecticidal methods — MISSIROLI (p 151) gives an account of the campaign undertaken against mosquitoes in Italy, where reliance has been placed on spray-painting of houses with DDT. The figures quoted show striking reduction of mosquitoes, of cases of malaria, and of deaths from malaria and from all causes. The reduction in deaths from all causes is probably a result of the reduction of enteric diseases consequent upon the wide destruction of house flies achieved by DDT.

Aziz (p 152) gives a detailed account of the work done during 1946 in the *Anopheles*-eradication scheme for Cyprus. Only part of the island was attempted in that year, but the work is to be extended later. DDT in oil was used as a larvicide, and as a residual spray in houses, pyrethrum was also used. The results were satisfactory though complete eradication was not achieved in this first year. The local anophelines are described.

The enormous control scheme undertaken in Greece in 1946, with DDT, is described by VINE (p 492). For hibernating mosquitoes residual spraying was practised with a 5 per cent DDT at 220 mgm per square foot, and for larvicidal work also 5 per cent DDT was used. Aircraft were used for marshes. These applications were made time after time from spring to autumn, and although comprehensive statistical data are not available, the amount of malaria was much less than the expected amount, some 80 per cent of the population at risk having been protected. In addition, flies and sandflies almost disappeared, but bees were little affected after blossom time. The effects of DDT on the 6 000 labourers were negligible.

LIVADAS *et al* (p 758) report on a special investigation they made to assess the results of this programme. They found spleen rates reduced to half the previous figures and parasite rates to one tenth, in unprotected areas the parasite rate had not declined.

LIVADAS (p 758) describes the campaign of the following year, when by house spraying and larvicidal methods, all with DDT, over 4 million people were protected. The mosquitoes were again controlled, but the house flies much less so.

A big programme of house spraying with DDT in the Veneto Provinces of Italy was followed by a great reduction in malaria (SEPULCRI, p 758).

BERBERIAN (p 870) has used 5 per cent DDT in kerosene with success as a residual spray and as a larvicide, in Lebanon where the vectors are *A. sacharovi* and *A. superpictus*.

AFRIDI and BHATIA (p 493) have used DDT as a residual spray near Quetta, India with success. At a concentration of 25–38 mgm per square foot there

was apparently a reduction in the incidence of malaria the anophelines concerned were *A. superpictus* & *calliciax* and *A. stephensi*.

PURI *et al.* (p. 154) have published four useful papers, in which they show the value of DDT in oil or turpentine as a larvicide in ricefields, pits and streams, and as a residual spray (especially against *A. minimus* and *A. superpictus* in Bengal and Baluchistan respectively). They give details of amounts used.

In an investigation of the effect of spray treatment of African houses with pyrethrum or DDT in kerosene Muirhead Thomson (p. 405) has shown that though the numbers of *A. gambiae* and *A. moides* caught in houses after treatment is reduced, this is rather due to the fact that they are driven to rest outside after feeding even more than they normally do. Low house catches therefore, do not necessarily indicate heavy mortality or reduction of biting activity: these mosquitoes still seek human blood, but they do not normally rest much within the houses and a heavy dose of kerosene on the wall has a repellent effect.

In field trials in Sierra Leone DAVIDSON (p. 157) has demonstrated that Gammaxane (0.5 per cent. solution at 10 mgm. per square foot of surface) used as a residual spray is very effective in reducing for 6 months the mosquito population in houses (*A. gambiae*, *A. moides* & *A. fuscipes*). He found, however (p. 158) that in the group of villages sprayed there was little change in the malaria rate as a result of these measures.

TOYANING *et al.* (p. 241) conducted a campaign of residual DDT spray in a malarious district of Mauritius where *A. fuscipes* is the chief vector. They demonstrated great reduction in the numbers of *A. fuscipes* caught in the sprayed houses after 3 treatments of 178, 112 and 150 mgm. DDT per square foot, and they found some reduction in the parasite rate of the people.

NAIR (p. 1083) reports marked reduction in the anopheline vectors (especially *A. latifer*) in a town in Malaya after DDT residual spray had been used three times in three months. The effect on spleen rates and parasite rates was also good.

WATERHOUSE and VINESTON (p. 975) have tested pyrethrum and other sprays against various mosquitoes including *A. punctulatus*, *A. tritaeniorhynchus* and show that a spray containing 0.14 per cent. pyrethrum gives good knockdown. This was used by the Australian Army authorities until the advent of DDT which was used to reinforce the pyrethrum as an all-purpose spray.

BING *et al.* (p. 45) show that DDT residual spray at 100 mgm. per square foot was effective in reducing the numbers of *A. punctulatus*, *A. tritaeniorhynchus* and *A. subpictus* found in houses in villages of New Guinea even after 4 months the numbers were only 5 per cent. of the numbers found in adjacent unsprayed villages.

LEST (p. 682) shows how effective a combined campaign of DDT residual spray and DDT in kerosene as a larvicide was against *A. farauti* in Espiritu Santo, New Hebrides, during the war.

MCCATLEY *et al.* (p. 700) have shown that for DDT to be effective against *A. quadrimaculatus* as a residual spray in houses it must be applied not only to likely mosquito resting places (under-sides of furniture etc.) but also to wall and ceilings as a whole.

FLETCHER and KRACE (p. 701) concentrated on *A. quadrimaculatus* on all houses and all likely outdoor resting places of *A. quadrimaculatus* over large area, in the hope that this might be more effective than residual spraying of houses combined with the use of field larvicides. The results obtained encouraged this hope though eradication was not achieved.

BRADLEY and FARR (p. 42) as a result of a second season's residual DDT spray programme found that at a concentration of 700 mgm. per square foot

over 98 per cent of houses (in southern U S A) were free of *A. quadrimaculatus* 4 months or more later, and that fewer of the anophelines taken in sprayed houses showed evidence of human blood than of those taken elsewhere. In comment, GORDON refers to British work on *A. gambiae* which indicates that at least 200 mgm per square foot are needed for effective results.

As a result of experience of treating with DDT emulsion the insides of all buildings in an area near the Wheeler Reservoir (Tennessee Valley) HINMAN and CUTKOMP (p 156) conclude that this procedure offers better protection than mosquito-proofing against malaria transmission. *A. quadrimaculatus* is the mosquito concerned. CUTKOMP (p 156) has compared the immediate and residual action of several insecticides, but for details the original should be consulted.

WEATHERSBEE *et al* (p 1063) have observed that at concentrations of DDT of 40 mgm per square foot to animal houses the surface remained free of *A. quadrimaculatus* for 27 days, at 200 mgm the period was 135 days.

LINK (p 43) has made blood surveys in South Carolina, and also in Porto Rico on populations in areas where residual DDT spray was used, and on control populations. The vectors were *A. quadrimaculatus* and *A. albimanus* respectively, and the results indicated a reduction in malaria, but the doses of DDT are not given.

A description of the malaria situation of British Guiana, and of the breeding habits of *A. darlingi*, the chief vector, is given by STAGE and GIGLIOLI (p 308), who show that DDT applied as a residual insecticide is most effective against this mosquito. GIGLIOLI (p 976) states that in the parts of British Guiana in which DDT residual spray has been extensively used, *A. darlingi* has been eradicated. The aim is to treat all buildings with 150 mgm DDT per square foot at intervals of 8 months or even longer.

As a result of their experiments GALVÃO and DAMASCENO (p 683) think that application of DDT (195 mgm per square foot) as a residual insecticide in wooden houses at intervals of 4 months should be effective against *A. darlingi*, where breeding takes place throughout the year.

A DDT spray campaign against *A. darlingi* in Brazil was very effective in reducing the number of mosquitoes in the houses, and the number of cases of malaria (BRAGA *et al*, p 408).

The use of DDT as a residual spray was apparently successful in reducing the incidence of malaria along the coast of Peru (CORRADETTI, p 871).

KUCHER (p 307) writes of a Russian insecticide derived from coal tar.

Larvicidal methods—Experiments in England by JOHNSON and WALTON (p 306) showed that the critical density of application of DDT for the control of anopheline larvae is about 40 gm per acre (10 mgm per square metre), below which results are unreliable, especially if there are reeds. Oil solution is better than emulsion.

JOHNSON and GOODMAN (p 45) show that DDT in oil, with a spreading agent, gives satisfactory results against larvae of *A. quadrimaculatus* at the rate of 75 gm DDT per acre. The amount of oil needed is very much less than when oil without DDT is used.

In an enquiry on the effect of DDT (used as a larvicide) on wild life, TARZWELL *et al* (p 46) show that at 0.1 lb per acre it had considerable effect on insects, at 0.4 lb an effect on fish, but not much on birds, rats, rabbits, etc., or on plankton.

DEONIER *et al* (p 581) have produced some experimental evidence that DDT applied to mud is effective against mosquito larvae which appear after subsequent flooding.

SAUTER *et al* (p 45) have obtained very fine suspensions of DDT by treating with supersonic waves the emulsions of benzene solutions mixed with water.

PUTNAM and HACKETT (p. 152) give an account of the antimalaria work done in Albania from 1929 to 1933, when drainage or filling of swamps, training of streams, alterations of salinity and Paris green were the means used for control. They describe the habits of the common vectors.

DE MEYLOU and THOMP (p. 149) have noted that quinine and mepacrine will inhibit the growth of larvae of *Aedes aegypti* but that this inhibition is reversed if brewer's yeast is added in quantity to the medium.

Malaria of Birds

Sporozoites of *P. gallinaceum* from mosquitoes which have been grown up in saline or Ringer solution are soon harmed if kept at 4°C. and still sooner at 37°C. but TONKIN (p. 243) has shown that in plasma or plasma saline they survive with no apparent change for more than 14 hours.

WHITMAN (p. 1065) has been able to preserve sporozoites of *P. gallinaceum* for 72 hours by suspending them in an extract of washed chicken erythrocytes. This is an important step in experimental work.

LEWERT (p. 582) has grown *P. gallinaceum* in tissue culture and has observed that subinoculation into chicks led to exclusively exoerythrocytic infection.

GRAMICCIA and BLACK (p. 665) cultivated *P. gallinaceum* in tissue culture from birds which had been infected by blood inoculations of trophozoites; not by sporozoites. Typical exoerythrocytic forms were found in macrophage-like cells.

MAXWELL (p. 495) discusses the glucose metabolism of *P. gallinaceum* and the action of antimalarial agents on it. Details should be sought in the original.

The technique of rearing and feeding *Aedes aegypti* used for transmission of *P. gallinaceum* is described in detail by JOHNSON (p. 309).

HAAS and ARDIS (p. 310) have succeeded in transmitting *P. gallinaceum* by *A. quadrimaculatus*; this has not previously been done.

Quinine and pabidine administered to *Aedes aegypti* by allowing them to feed before and after infection on sugar solution containing the drugs were shown by JOHNSON and ARDIS (p. 1065) to exercise marked inhibitory action on the development of sporozoites of *P. gallinaceum*.

WHITMAN (p. 877) has shown that the hydronaphthoquinone M 2279 has some effect on oöcyt formation if ingested by *Aedes aegypti* within 48 hours of an infective feed of blood containing *P. gallinaceum*. It has no effect on sporozoites. CLARKE and TRELLER (p. 696) have experimented with a hydroxynaphthoquinone in *P. gallinaceum* infections. It is very active against the earliest phases of the developing parasite and there is strong evidence that the effect is against the sporozoite itself. Complete prophylaxis could be obtained. It is also active against late exoerythrocytic forms and against blood forms.

TONKIN and HAWKING (p. 243) have studied the technique of testing drugs on *P. gallinaceum*. For sulphadiazine the best results were obtained when the drug was administered over a period of 4 days.

TERILAN (p. 767) describes his method of using *Aedes aegypti* and *P. gallinaceum* in experiments to determine the antimalarial activity of various drugs.

PARAFSKY (p. 47) reports his experiments with *P. gallinaceum* infection of chicks, induced by either sporozoite inoculation or blood inoculation. Details are given in the original abstract. Treatment with quinine did not eliminate all trophozoites, and exoerythrocytic forms were found in birds so treated; moreover it seems that the blood trophozoites increased as a result of increase of the exoerythrocytic forms. Only the blood forms seem to stimulate immunity.

KROPPERS (p. 156) has found some light resistance to quinine in *P. gallinaceum* in chickens treated with small doses.

WILLIAMSON and LOURIE (p 48) give details of their experiments which showed that resistance to paludrine developed in *P. gallinaceum* (as a result, probably, of mutation) in chicks treated with that drug in two schedules, but that resistance to quinine, mepacrine, M 3349 or sulphadiazine could not be provoked

BISHOP and BIRKETT (p 1066) in comparable tests on *P. gallinaceum* in chickens, showed that with relatively small doses of the various drugs there was no development of drug resistance to mepacrine, only slight to pamaquin, but 40-fold increase to paludrine. This resistance to paludrine persisted on subinoculation

PIFKARSKI (p 1067), similarly, failed to produce resistance to mepacrine

Exposure of chicks infected with *P. gallinaceum* to atmospheres containing excess of oxygen did not benefit them (TERZIAN and SAXE, p 496)

TRAGER (p 159) discusses the relation of biotin and a fat-soluble substance having the same properties, and found in plasma, to the course of avian malaria, details should be sought in the original

TALIAFERRO and TALIAFERRO (p 768) show that nitrogen mustard, which is toxic to lymphocytes, has a decided action in damaging the parasitocidal mechanism of acquired immunity when administered to chickens either shortly before or shortly after infection with *P. gallinaceum* or *P. lophurae*

KIKUTH and MUDROW (p 47), in a paper published in 1939, discuss the early stages of *P. cathemerium* development after injection of sporozoites

SIMPSON (p 873) has studied the cycle and course of *P. cathemerium* infections in ducks and canaries

BECKMAN (p 1067) has shown that if sporozoites of *P. cathemerium* are incubated with canary blood and hen blood, the latter exerts a strong inhibitory action on them, preventing infection of birds subsequently injected, whereas the canary blood has no similar action

WALKER *et al* (p 687) describe the technique they adopted during the war for testing drugs against *P. cathemerium*, for details the original should be consulted

WALKER and RICHARDSON (p 688) discuss the synergic effects observed, in *P. cathemerium* infections, between the 8-aminoquinolines (plasmoquine, pentaquine) and certain naphthoquinones. These effects were evident in curative treatment, but much less so in suppressive treatment, which suggests differences in the mechanism of the two processes

GINGRICH (p 980) found a progressive decline in the immunity acquired by canaries after infection with *P. cathemerium* by injections of blood, and cured by drugs. Immunity had disappeared completely in 8 months

REDMOND (p 769) has studied the electric charge of red blood cells in *P. relictum* infections of pigeons

MICKS (p 497) shows that two strains of *P. elongatum* lost the power to produce gametocytes: one had been passed through ducks, the other through canaries

THOMPSON *et al* (p 1066) show that injected radio-active iron has no effect on *P. lophurae* in ducks or *P. cathemerium* in canaries

RIGDON (p 49) thinks that accumulation of CO₂ in the body at the peak of infection may be the cause of the sudden fall in number of parasites after the crisis. In comment, GARNHAM remarks that the experiments quoted (with *P. lophurae*) are not entirely convincing

RIGDON and McCAIN (p 409) discuss some of the factors which influence the degree of parasitaemia in ducks infected with *P. lophurae*, especially the oxygen and CO₂ content of the blood. Details should be sought in the original

RIGDON and ROSTORFER (p 979) consider that the anaemia caused by *P. lophurae* in ducks is due to destruction of mature erythrocytes and their replacement by the less efficient erythroblasts. The latter are not well suited to the needs of the parasites

TOWKIN and HAWKING (p. 409) describe erythrocytic forms of *P. lophurae* grown in tissue culture of turkey liver.

THOMSON *et al.* (p. 49) have found it possible to immunize ducks with *P. lophurae* or *P. cathamerum* killed by formalin, injected intramuscularly in a medium of paraffin oil with killed tubercle bacilli and an emulsifying agent. Repeated injections protect for about 6 months—the vaccine prevents death and reduces parasitaemia.

HAIRA (p. 769) records the plasmodia found in common Egyptian birds.

Malaria of other Animals

The physiological changes in the blood of monkeys infected with *P. knowlesi* are described by OVERMAN and FRIEDMAN (p. 766). In the stage of heavy infection the red cells are reduced in number and carry little oxygen—these anoxia results and is the cause of death.

FREUND *et al.* (p. 766) have succeeded in inducing a considerable degree of immunity in monkeys by injecting a vaccine of *P. knowlesi* with certain adjuvants.

Soluble antigens from *P. knowlesi* and *P. lophurae* have been used for complement-fixation tests—the former was useful in homologous infections only the latter in both (DAVIS p. 767).

HUFF and COULTON (p. 782) record their attempts to find, without success, pre-erythrocytic stages of *P. rimeri* and *P. cynomolgi*.

RODMAN (p. 978) has shown that *P. rodhaini* of the chimpanzee is transmissible to man and *P. malariae* to the chimpanzee. In comment, GARNHAM remarks that the two should be regarded as identical.

VIERCKE and LIEB (p. 979) describe *P. longi* a new species from a rodent to the Belgian Congo.

The developmental cycle of *Hepatoscydes luchi* in the monkey has been worked out and described by GARNHAM (p. 833). Details should be sought in the original.

Charles W. Verelst

MALARIA

DEGLEYMAN H. & VAN THIEL, P. H. L'épidémie du paludisme à Middelbourg dans les années 1940 à 1946 y compris un examen de porteurs de parasites [Malaria Epidemic in Middelbourg 1940 to 1946, including an Examination of Parasite Carriers.] *Bull. Soc. Path. Exot.* 1948, v. 41, Nos. 9-10, 591-641.

It was in 1900 that malaria was first proved to be present in Zeeland in the Netherlands. There were 200 primary infections in that year. Thereafter the disease disappeared from the province till 1920-1924 when fresh outbreaks occurred. In 1939 sporadic cases still occurred, the precursors of an epidemic which commenced in 1940 with 40 cases. Maximum prevalence was in 1943 with 900 primary cases. The epidemic ceased in 1945 when only 14 cases occurred.

The malaria outbreaks in Middelbourg differed in certain respects from those occurring in other parts of the Netherlands. The maximum prevalence was in August sometimes in July but never in May-June—most cases were single cases, even when these occurred in households with many children—the disease was not specially prevalent among children.

The spleen index among school children was remarkably low—2.7 per cent. During this examination only one case was discovered that had not previously been notified by local doctors. In September 1941 cellars in the middle of

Middelbourg, that had been exposed by the bombardment of the town in May 1940, were found to be prolific breeding places of *A. maculipennis atroparvus*. It is remarkable that this biotype should have selected such freshwater breeding places, some of them shaded from sunlight, when saline breeding places were readily accessible in the neighbourhood. The extension of malaria had already begun when this unusual source of supply of the anopheline vector first became operative.

Control measures included (1) administration of quinine (1 gm. for adults) on each of two successive days each week, from mid-August to the end of October, to all persons who had suffered from malaria during that or the preceding year, with special attention to the known 65 parasite carriers. (2) spraying the bedrooms of these persons every 15 days with shelltox, during the same period of time, (3) the abolition of mosquito breeding places in the cellars of the town.

One of the reasons why Middelbourg alone, and no other part of Zeeland, suffered from the epidemic was the arrival of infected persons. The barracks were occupied by German troops, many horses were stabled in the middle of the town and attracted large numbers of anophelines.

The final extinction of malaria was probably accelerated by the inundation in October 1944. In the summer of 1945 practically the whole island was under sea-water. No mosquito breeding places were left. There was not a single fresh infection of malaria in Middelbourg in either 1946 or 1947.

Norman White

JAUVOU, C. & TOUMANOFF, C. Compte rendu d'un sondage malarologique effectué en Corse (16-30 Août 1947) [Cursory Malarial Survey in Corsica] *Bull. Inst. Nat. Hyg.* Paris 1948, July-Sept., v. 3, No. 3, 468-81.

A visit of two weeks duration was paid by the authors to Corsica to enable them to obtain preliminary information as to the extent to which war-time events, including the temporary cessation of antimalarial work, had influenced the malaria endemicity of the Island. The inspection was made in the latter half of August, 1947. Visits were paid to a few localities in both the eastern and western sides of the Island.

Spleen and parasite rates of the few places visited were on the east coast 12.8 and 48.6 per cent, and on the west coast 9.6 and 32.2 per cent. There was evidence of locally acquired malaria in Ajaccio, a town which was formerly considered to be almost free from malaria. Gamete carriers were relatively numerous. *A. maculipennis labranchiae* and *A. sacharovi* were found on both sides of the Island. One infected *A. m. labranchiae* was captured. A further more detailed survey was to be carried out in the late autumn.

BLONOMINI, G., SICCA, G. T. & MANFREDI, M. La malaria all'isola d'Elba [Malaria in the Island of Elba] *Riv. Italiana d'Igiene* 1948, Jan-Feb., v. 8, Nos. 1/2, 1-12, 1 map & 1 chart.

Between the world wars, malaria was a disease of little account in the Isle of Elba. After the first war, a considerable outbreak occurred in connexion with constructional work on a cement factory, this rapidly subsided. In 1943, there was a noteworthy increase in malaria prevalence and the incidence increased in the following years. The Commune of Portoferraio in the north of the Island was chiefly affected. This exacerbation of the disease was attributed in part to the return of soldiers from infected war zones, the arrival of troops from Corsica and Sardinia, and passage of Moroccan troops through the Island. The authors

were invited to study the situation and carried out an investigation that lasted from September 1946 to October 1947. Their findings are summarized in this report.

The only anopheline found was *A. macbryani labanchiae*. This marks the northern-most limit in Italy of the distribution area of this sub-species. Its area of distribution in the Island are circumscribed, breeding places are not numerous, and prevalence is not excessive.

Malaria cases occurring in 1946 and 1947 are given in graphic form. All were *P. fies* infections. Cases occurring in February and March were presumably infections contracted in the previous autumn. There is a steep rise in the curve which reached its height in July or August. Spleen rates of children were indicative of low endemicity.

A DDT campaign was started in June 1947. All houses, stables and out buildings, in the infected areas were sprayed. This appears to have cut short the epidemic but *labanchiae* was still found breeding in limited numbers. Antilarval measures were then superimposed. The measures were to be continued the following year and it was hoped that they would be successful in eradicating *Anopheles* and malaria from the Island. Norman White

For H. KONDI Athens, DANKAS C. DEPOULAY Margaret, LERGOPOULOS Theresa, BACI L. G., DAX, R., PITCHFORD J. SHIPLE Pamela & LANGTON Moira. Malaria and Blackwater Fever in Macedonia and Thrace in relation to DDT. *Ann. Trop. Med. & Parasit.* 1948, Sept., v. 42, No. 2, 153-72, 5 figs. & 1 map [71 refs.]

This is a record of a malaria survey carried out in Macedonia and Thrace during November and December 1946 to assess the relative cumulative effect of the nation-wide DDT campaign of the preceding year and of natural variation in malaria endemicity respectively, on the low malaria-rates in northern Greece since the severe malaria epidemic of 1941. The incidence of malaria in Macedonia has long been characterized by annual variations in intensity, probably connected with variations in anopheline density which is dependent on the rainfall in late winter and spring.

During the twenty four years 1923-48 there was a noteworthy overall decline in malaria morbidity in Macedonia, punctuated by occasional years of abnormal prevalence. As a measure of malaria incidence the authors use the percentage of malaria in total admissions to the Central Refugee Hospital and the Municipal Hospital in Salonika, the former of which is mainly occupied with rural populations. The mean malaria incidence for the twelve-year period 1923-34 was 17.5 per cent. for 1935-48 it was 10.6 per cent. In 1941 there was a major malaria epidemic that affected the whole of Greece. The incidence in Macedonia rose from 13.7 per cent. in 1940 to 28.4 per cent. in 1941. This epidemic occurred during the German occupation when there was much disorganization and acute food shortage. There was a rapid decline in malaria incidence in the following years: in 1945 it was only 3.5 per cent. The extensive use of atabrin (mepacrine) may have contributed to this decline. The DDT campaign was undertaken late in 1945.

A country-wide survey of Macedonia and Thrace was carried out during November and December 1946. 1,000 spleens were palpated and the blood of 7,000 school children and of 200 infants who had lived through only one transmission season was examined. The parasite-spleen ratio which in the past had usually ranged from 1:2 to 1:4 had fallen to 1:31 to 1:70. Evidence was obtained that DDT had contributed much to the remarkable reduction of malaria incidence in Macedonia and Thrace. The incidence in 1946 was only 1.7 per cent.

The greatly increased incidence of malaria in 1942 was not accompanied by a corresponding increase in the incidence of blackwater fever *Norman White*

MONTALVAN C, J A Paludismo en Guayaquil [Malaria in Guayaquil] *Rev Ecuatoriana de Hig y Med Trop* Guayaquil 1944, Apr, v 1, No 2, 131-60, 2 maps, 5 graphs & 1 fig

HUFF, C G Exoerythrocytic Stages of Malarial Parasites *Amer J Trop Med* 1948, July, v 28, No 4, 527-31 [19 refs]

This is an account of the various questions relating to the exoerythrocytic stages of malaria parasites. It was written before the demonstration of the hitherto hypothetical exoerythrocytic stages in mammalian malaria.

The points dealt with, which need not now be elaborated further, are —

"What are exoerythrocytic stages?"

"Why were they so long in being discovered?"

"What types of exoerythrocytic stages are known?"

"In what species have exoerythrocytic stages been demonstrated?"

"What about the claims for finding exoerythrocytic stages in human and simian malaria?"

"Do such stages really exist in human or simian malarial infections?"

"Do exoerythrocytic stages offer the means for any new approaches to old problems in malaria?"

"What is the significance of the exoerythrocytic stages in the life-cycle?"

BIJLMER, J & KRAAN, H Is the Gametocyte Production of *Plasmodium vivax* Influenced by Elimination of the Mosquito Passage? *J Trop Med & Hyg* 1948, Nov, v 51, No 11, 222-5

If *Plasmodium vivax* infection is transmitted serially by blood inoculation, the sexual cycle is eliminated and it is conceivable that the formation of gametocytes may decline or even cease. Some observations appearing to substantiate this effect have, in fact, been disproved when subjected to critical tests.

The authors investigated the problem at the Wilhelmina Hospital in Amsterdam and arrived at the following conclusions —

(a) The ability to produce many or few gametocytes is a strain characteristic in a given plasmodial species.

(b) In malaria, exclusively transmitted by blood inoculation, there occurs a diminished power of the parasite to produce gametocytes. The decline, in extent and rapidity of onset, varies with the strain in use. *H E Shortt*

GAUD, J Fréquence au Maroc et rôle vecteur possible d'*Anopheles sergenti*, Theo [Frequency and Possible Vector Role of *Anopheles sergenti* in Morocco] *Bull Soc Path Exot* 1948, v 41, Nos 7/8, 498-501, 1 map & 1 fig

During an anopheline survey of Morocco in 1947, the following species were found as larvae and adults: *A. maculipennis* [the subspecies is not stated, but it is presumably *labranchiae*], *A. sergenti*, which was surprisingly abundant, *A. turkhudi* (? *A. hispaniola*), *A. multicolor* and *A. claviger*, all these were house frequenters in different degrees. Other species taken were *A. marleri* (a new record for Morocco) and *A. constantii* from some new localities.

The distribution of *A. argenti* is indicated on a sketch map north, but it occurs near the coast as well as inland. The highest altitude at which it was captured was 1700 metres (approx. 5500 feet). It was prevalent between June and November and most abundant in September and October. Its relation ship to malaria transmission is uncertain. 33 dissections were negative proving nothing, but this species enters houses readily and after *A. maculipennis* is the most domestic anopheline.

The wings of the Moroccan form of *A. argenti* differ from the typical form in that the basal and peripical dark areas of the costa are so extended that in some specimens the two adjacent pale spots are obliterated, leaving only two pale costal spots.

BURGESS R. W. The Experimental Hybridization of *Anopheles quadrimaculatus* Say and *Anopheles maculipennis freeborni* Allen. Amer J Hyg 1919, Sept., v 43, No. 2, 171-2

"Hybridization between *Anopheles quadrimaculatus* Say and *Anopheles maculipennis freeborni* Allen under laboratory conditions is reported.

A. quadrimaculatus males mated with *A. maculipennis freeborni* females produced 30.3 per cent. fertile ova. The fertility of the opposite cross was only 2.0 per cent.

All larvae were small and weak and none survived beyond the third instar."

PRATT H. D. Influence of the Moon on Light Trap Collections of *Anopheles albimanus* in Puerto Rico. J National Malaria Soc 1918 Sept. 7 No. 3 21-20 6 figs.

Four years trapping records and observations on *Anopheles albimanus* are discussed in this paper. Charts are presented to illustrate the effect of moonlight on the catches in light traps.

Experiments with light traps of different light intensity showed that they attracted *A. albimanus* in numbers which varied according to the intensity of the light given out by the traps. When a single trap was used, the size of the collection varied with the "dark" and "bright" phases of the moon; the darker the night the greater the numbers of mosquitoes attracted. When an animal trap was situated near a light trap the light collections were then higher than those in the bait trap during the "dark" phase of the lunar cycle and approximately equal to, or lower than, those in the animal trap during the "bright" phase. The size of the collections from both types of traps fluctuated seasonally, but those from the light traps were also subject to cyclic fluctuation within each month. The suggestion is made that the mosquitoes do not use the light trap so well during the "bright" phase of the moon as during the "dark" phase. Animal traps may therefore give a truer conception of the trends in anopheline populations.

It is more difficult to determine an index for "satisfactory control" based on light trap collections alone, but it may be stated that, in general, little or no malaria transmission occurred when light catches averaged 1-5 *A. albimanus* per night during the "bright phases" and 5-20 during the "dark phases" of the moon. These figures are comparable with the single figure of 2 to 5 *A. albimanus* per animal trap per night given as the "satisfactory control" figure for military bases.

DEANE, L M, CAUSEY, O R & DEANE, M P. Notas sobre a distribuição e a biologia dos Anofelinos das regiões Nordeste e Amazônica do Brasil [Notes on the Distribution and Biology of the Anophelinae of the North-East and Amazon Regions of Brazil] *Rev. Serviço Especial de Saúde Pública* Rio de Janeiro 1948, May, v 1, No 4, 827-965, 6 graphs & 39 maps on 6 pls [34 refs.] English summary

The observations recorded in this paper were made by the authors from 1939 to 1944. Many thousands of anopheline mosquitoes, larvae and eggs were examined and thirty-six species were found. A number of identifications were confirmed by laboratory-bred specimens. The distribution of each species is given in tables and shown on maps. Other tables show the results of salivary gland and stomach dissections for malaria infections, the results of hourly collections and collections in animal shelters and human dwellings are also given. The results of hourly captures of *Anopheles darlingi*, *A. albimanus* and *A. aquasalis*, both indoors and outside, are shown on six graphs.

A. darlingi and *A. aquasalis* are the only species of real importance in the transmission of malaria in these regions, the African invader *A. gambiae* has been eradicated.

A. darlingi is the most domestic species and previous observations that this anopheline normally enters houses during the late hours of the night were confirmed, though two peaks of entry, one at sunset and one just before sunrise, were often noted. Where the species was abundant, it was captured feeding outside as well as indoors at any time, even during the hottest part of the day, but where it was rare it could only be found indoors during the late hours of the night or at dawn. Comparative captures yielded larger numbers on horse than on man, indicating that this species is perhaps less anthropophilic than it was thought to be. Among 1,600 dissections of females of *A. darlingi*, 28 (1.8 per cent) were found to be infected, though for different localities the rates varied from 0 to 50 per cent. Where the species was abundant the infection rate was low and the opposite was also true.

Whereas *A. darlingi* is a freshwater breeder, *A. aquasalis* larvae were usually found in brackish water, both along the coast and as far inland as 140 kilometres from the sea. *A. aquasalis* invades houses and feeds readily on man in the north-east of the country but in the coastal areas of the Amazon region it is far less domestic. It is a malaria vector, either alone or together with *A. darlingi*, but in the areas investigated it is not so important as *A. darlingi*, because it is less domestic in habit, and because it is dangerous only when abundant.

Two forms of *A. albimanus* were encountered. One of them (var. *domesticus*) was found feeding frequently on man during a malaria epidemic in an area where it was the only abundant anopheline, in other places *A. darlingi* and *A. aquasalis* were also present. The other form [not named] feeds on animals and does not seem to take any part in the transmission of malaria.

One other anopheline, *A. pessoai*, (perhaps synonymous with *A. brasiliensis*) was once found infected with sporozoites. There is no evidence that any of the other species is a natural vector of malaria in these regions.

PITTEMBRIGH C. S. The Bromeliad-Anopheles-Malaria Complex in Trinidad.
1. The Bromeliad Flora. Reprinted from *Evolution* 1948 Mar v 2
No. 1 58-69 7 figs. (4 on pls.) [27 refs.]

The Anopheline mosquitoes of the subgenus *Anopheles* breed in water held among the leaf bases of Bromeliad plants, growing as epiphytes on trees in Tropical America. The present paper is a contribution to the natural history of these plants, of which fifteen genera and a large number of species are found in Trinidad. The author has produced an interesting classification of the types of environment which they inhabit. Some grow on rock and root in soil; others have developed "nutritive independence" - they grow on limbs of trees, hold water and humus among their leaf bases and exploit these materials. The distribution of species is determined rather by light than by atmospheric moisture.

MARTINEZ MUJICA, Celia. Reticulo endotheliosis palúdica. [The Reticulo-endothelial System in Malaria.] *Medicina* Mexico, 1948 Oct 10 & 25 Nov 10 & 25 v 28 Nos. 563 566 567 & 568 417 '78 451 '7 459 '79 481-8 10 figs. [Numerous refs.]

This article deals fairly exhaustively with the reticulo-endothelial system, not only as regards malaria, but more generally. The whole consists of ten sections - but much of it is recapitulatory and brings together our knowledge of the subject and sums up the latest views on it without contributing much that is really new. In fact, a good deal has already been incorporated in the textbooks.

Section I sketches briefly the history of our knowledge of the r.e.s. from the time of Rattier's observations in 1890. Section II describes the normal histology of the system in the blood-vessels, the spleen, lymphatic glands, bone-marrow, the connective tissues, lungs, liver, brain, etc. Next follows an account of the physiology of the system as regards malaria, phagocytosis, haematolysis, destruction of red and white corpuscles and platelets, and haemopoiesis, the development of immunity or rather the prevention of its development when the r.e.s. is blocked. In Section III the pathology of the r.e.s. is considered in connexion with infective diseases in general - (a) taking up organisms by the cells of the system. This is followed by a description of the part it plays in paludism, with photomicrographs showing cells of the capillaries blocked by parasites, and of the spleen and liver in malaria and of the xer erythrocytic forms of *P. cathemerium* and *P. circumflexum* in the canals. There is presented a very clear schematic presentation of the parasite cycle - the xer erythrocytic cycle, the cryptozoites of Huff, the schizontic cycle of Golzi and the sporogonic cycle of Ross (so named by the author). Section VI treats of the r.e.s. and the clinical manifestations of malaria and states that the anaemia associated with the disease is not due solely to destruction of red corpuscles, but also to blocking and injury to the haemopoietic organs. Section VII discusses the rôle of the r.e.s. in malaria immunity - especially in the spleen, liver and bone-marrow - by causing concentration of histocytes and hyperplasia of them and in stimulating phagocytosis by them. Next follows remark on the laboratory diagnosis in regard to the r.e.s., indicating that the ordinary method is inadequate to demonstrate malarial reticulo-endotheliosis, and once taking the reactions of Henry and Soherus. The epidemiology of malaria and its relations with the r.e.s. are evidenced (Section IX) by the plenic and parasitic indices. Finally the subject of treatment is considered and it is shown that parasites not destroyed in the blood find refuge in the cells of the r.e.s., where they continue to develop and remain until conditions become

favourable, when they are discharged into the blood-stream, attack fresh corpuscles and set up a relapse. At present, says the author, we lack drugs which will attack the reticulo-endothelial phase of the parasite, but experiments are being undertaken to produce synthetically some product which will effect this. In conclusion, it is recommended that "malarial reticulo-endotheliosis should be investigated by all possible means, including the reactions of Henry and Soberón, in persons exhibiting mental disturbance of sudden onset who suffer or have suffered, from malaria, or who reside in, or have come from, malarious districts, if no other, obvious, cause for the disturbance can be found."

LIPPI, M. L'attività secretoria dello stomaco nella malaria cronica [Secretory Activity of the Stomach in Chronic Malaria] *Acta Med Italica* 1948, Sept v 3 No 9, 231-4 English summary (10 lines)

This paper concerns twenty patients suffering from chronic malaria, all of whom had enlargement of the spleen and liver, well marked hypochromic anaemia and leucopenia. In each case a tube was introduced into the stomach in the early morning after the night's fast and left *in situ* till four samples of the gastric secretion had been obtained, at intervals of half an hour. In all samples there was a noteworthy decrease of total acidity and of hydrochloric acid content. Thus the author attributes to the changes in the blood, bone-marrow, liver and spleen that characterize chronic malaria. He thinks, too, that splenic hyperfunction may inhibit thyroid stimulation of the gastric secretion.

MONTALVAN, C. J. A. Algunas consideraciones sobre el diagnostico clinico del paludismo en comparación al resultado del examen de sangre [The Clinical Diagnosis of Malaria compared with Examination of Blood Films] *Rev Ecuatoriana de Hig y Med Trop* Guayaquil 1944 Apr, v 1 No 2, 161-6 2 figs

ZAKI, A. The Value of Tyrosine Index in Malaria and other Endemic Diseases in Egypt. *J Roy Egyptian Med Ass* 1944, Aug v 27, No 8, 243-50 [Reed 13 Dec, 1948]

- ' 1 The tyrosine serum index in pure cases of malaria is not always increased
- ' 2 Other parasitic diseases increase the tyrosine index especially *S. mansoni* infection. The index was also definitely increased in cases of hypertension and pellagra
- ' 3 It is very difficult to find pure cases of malaria in Egypt as the great majority of the rural population are very often infected with parasitic diseases and therefore tyrosine cannot be relied upon in the diagnosis of malaria.

CIUCA, M., BALLIF, L., CHELARESCO, M., CONSTANTINESCO, C. & TIMIŞESCU, A. Recherches comparées sur l'infection expérimentale, en but de malarithérapie, des malades appartenant respectivement à une région non paludéenne (Bucovine) et à une région endémique (Moldavie) [Comparative Study of Infection as a Result of Malaria Therapy of Patients from a Non-Malarial (Bukovina) and a Malarial (Moldavia) Region] *Arch Roumaines Path Expér et Microbiol* 1945-1946-1947, v 14, Nos 1/4, 193-206, 10 charts

This short paper makes some interesting comparisons between the relative susceptibility to the same strains of malaria of two populations in Roumania, one from an endemic area, Socola in Moldavia and the other from a non-endemic area, Bukovina. The patients reported on in these series were undergoing

treatment by therapeutic malaria and the data are strictly comparable as the malarial strains used were identical, *P. vivax* T. B. Hoar and *P. malariae* (P).

The results of the comparison showed that the patients from the non-endemic area had a markedly lower resistance to infection by these strains as evidenced by the following findings:—

- (a) They gave a hundred per cent. infection rate as compared with 83.1 per cent. in the case of those coming from the endemic area.
- (b) The incubation period was shorter
- (c) The degree of parasitaemia was greater
- (d) Anti-malarial drugs took longer to cause disappearance of the parasitaemia, at least in the case of infection with *P. malariae*

CIUCA, M. BALLIU, L. CHELARESCO, M. VRABIE, M. & MONTEANT VASILIU, F. Particularités régionales de l'infection paludéenne utilisées en but de traitement (malaria-thérapie) [Regional Factors affecting the Malarial Infection acquired as a Result of Malaria Therapy]. *Arch. Roumaines Path. Exptl. et Microbiol.* 1945-1946-1947, 14 Nov. 14, 207, 172 graphs.

This is practically a repetition of the previous paper the results being those obtained in another non-endemic area of Rumania where only scanty sporadic cases of malaria occur (Sibiu, Transylvania).

The findings confirm previous experience that patients from non-endemic areas have less immunity to malaria than those from endemic areas.

JOYCE, M. D., EYLES, D. E. & BLACKSBY, R. W. Studies on Imported Malaria. 10. An Evaluation of the Foreign Malaria Introduced into the United States by Returning Troops. *J. National Malaria Soc.* 1948 Sept. 7 No. 3, 171-85. [38 refs.]

Nine reports on studies in the United States of returned military personnel with malaria acquired overseas have previously been published, and summarized in this *Bulletin* [1946, 43, 3, 1002; 1947, 44, 773, 489; 1948, 45, 204, 298, 859, 1052, 1053]. This tenth report summarizes the findings of the entire programme of studies. The observations were carried out in ten Army and Navy hospitals and foreign strains of malaria were used in the treatment of neurosyphilis in eight other institutions. About 1,000 members of the Forces with relapsing malaria were examined, another 1,000 patients or volunteers were infected with one or other of the malarial strains isolated. There was no infection with *P. malariae* and only 8 cases of *P. falciparum* infection. One of the latter from Guadalcanal infected 4 m. *frankform* and another from Africa infected 4 *quadrinucleatus*. Most of the studies concerned *P. vivax*.

No consistent morphological differences could be detected between imported and indigenous strains of *P. vivax*. In two different *P. vivax* infections from New Guinea, forms resembling *P. ovale* were found on a few occasions but their occurrence was transient: they were probably abnormal forms of *P. vivax*.

There was but little heterologous immunity between *P. vivax* infections from the South Pacific, China-Burma India theatres and from the United States. One infection from New Guinea showed little immunity to another strain from the same area. Prepatent and incubation periods were shorter in infections with Mediterranean than with Pacific strains.

American Negroes are resistant to *P. vivax* of both Pacific and Mediterranean origin. In one study 31 per cent. of Negroes bitten by infected mosquitoes became infected as compared to 85 per cent. white patients.

When the fever first reached 100°F the number of parasites of Pacific strains averaged only 21 per cmm, the average number of parasites of Mediterranean strains was 45. Peak parasitaemias, averaging about 14,000 per cmm, were usually attained in the second week and were generally higher in Pacific than in Mediterranean infections. Maximum temperatures (average 105°F) tended to occur several days earlier than maximum parasitaemias. In tertian fevers the periodicity, average time between fever peaks, was 44.4 hours for four Pacific strains and 45.1 hours for one Mediterranean strain; none had a 48-hour periodicity.

Two hundred patients with delayed primary attacks were studied, mostly from New Guinea. The delayed primary attack occurred 49.1 days (average) after cessation of suppressive mepacrine. The parasite-fever thresholds in 65 patients were 730 parasites per cmm in delayed primary attacks and 1,980 in subsequent relapses, both much higher than in induced attacks with similar strains.

The foreign malarias responded well to treatment, of the commonly-used drugs, chloroquine was the most effective, quinacrine next, and then quinine, the poorest.

A smaller proportion of Mediterranean malarias relapse than of those from the Pacific. With a Pacific strain (Chesson) it was found that the greater the sporozoite inoculum, the shorter the prepatent period, the greater the relapse rate and the shorter the interval between relapses.

The comparative susceptibility to foreign *P. vivax* malarias of five anophelines, (the infective index of the most susceptible being expressed as 100) was found to be *A. m. freeborni* 100, *A. punctipennis* 86, *A. quadrimaculatus* 84, *A. p. pseudopunctipennis* 41, *A. albimanus* 2. Some foreign strains have been maintained unpaired through many man-mosquito transfers; they have very readily adapted themselves to new mosquito hosts.

Compared with indigenous strains, foreign malarias relapse more promptly after treatment of primary attack and produce a greater number of relapses. Parasitic relapses are not always accompanied by symptoms; the total time of asymptomatic parasitaemia is considerably greater than the time of symptomatic parasitaemia. In general the number of gametocytes was found to be a fairly constant proportion of total parasites present. The patient with asymptomatic parasitaemia is the one most likely to spread the disease in the conditions prevailing in the United States.

In 1945 there may have been in the United States as many cases of foreign *P. vivax* malaria as there were cases of indigenous strains (estimated at about 20,000).

SANDERS, J. P. & SANDERS, J. C. Intravenous Quinine in Post-War Malaria. *Med. Times* New York, 1948, Nov., v 76, No 11, 465-9.

A study of 271 cases of chronic malaria, 259 being civilians and 12 ex-servicemen. No attempt was made to identify the type of parasite although it is considered that the majority were of the benign tertian or tertian [*sic*] variety. Diagnosis was made largely from the history, symptoms, and physical signs; parasites [variety not stated] being found in only 72 patients in spite of routine examination of thick and thin films repeated many times in some

instances. Most of the patients had a leucopenia and high count of small lymphocytes while the spleen was almost always enlarged and tender.

Intravenous injections of 5 to 15 grains of quinine dihydrochloride in 100 cc. of 5 to 10 per cent. glucose were given the usual dose of quinine being 10 grains. Injections were usually repeated after 2 or 3 days, although occasionally they were given daily the number and frequency being determined by the patient's reaction and condition.

Among the 289 civilian cases a history of previous attacks was given in 64 per cent. Headache was the most prominent complaint although as might be expected, symptoms of almost every known disease were complained of, and many cases of resistant cough for which the patients had been treated for tuberculosis cleared up under treatment.

One patient had 12 injections and 3 patients had more than this number. The highest age group was over 50 (71 patients) while 22 were under 20. "Coloured people" numbered 34. Of the 1 ex-servicemen most had taken atabrin [mepacrine] while abroad and received other medication at some time.

The authors claim for this method of treatment —

(1) Complete relief of all symptoms in practically every case.

(2) Toleration in all age groups especially the aged.

(3) A general tonic effect possibly due to the glucose.

(4) Decrease in toxic effects while many of the side effects of quinine by mouth are avoided.

(5) Safety in allergic subjects although a few patients had to discontinue treatment on this account. Any reactions noted were not usually serious. Only 22 per cent of relapses were reported within two years.

[As the authors point out it was impossible to exclude reinfection in Louisiana and it must be remembered that 178 cases had other treatment by mouth, e.g. quinine quindine totaquina mepacrine atabrin. It is rather difficult to assess the value of this method for 1.] C. F. S. 424

MARSHALL, P. B. & ROGERS, E. W. The Determination of Quinine Degradation Product in Blood, and its Absorption in the Chick. *Biochem. J.* 1943 v. 43 No. 3 414-16 1 fig.

(1) A method for the quantitative determination of quinine degradation product (QDP) sensitive to 5 μ g. is described.

(2) The red-cell concentration of QDP in chicks during 7 hr. following oral doses is approximately the same as that of an equal dose of quinine indicating that the previously observed higher antimalarial activity of quinine is due to higher specific activity on the parasite and not to superior absorption in the host.

CITCA, M., SOFLETE, A., CONSTANTINESCU, P. & TERITEANU, N. Preliminary Note on the Therapy of Malaria with Paludrine in Experimental Infection by Inoculation of Infected Blood. *Bull. World Health Org.* 1944 v. 1 No. 2, 301-7.

A Rumanian strain of *P. vivax* that had gone through 279 passages was used. Forty patients were inoculated. Of these 8 received one dose of 100 mgm. paludrine 7 between the 4th and 8th days of fever and one after he had had paroxysms for a fortnight. In 7 cases fever disappeared within 24 hours of the administration of paludrine. In the other temperature was normal 3 days after the drug was given. In 2 cases parasites were absent from thick drops on the third day, in 4 on the 4th and in 1 on the 5th day. Twenty-four

patients were treated with 200 mgm of paludrine for 7 days, the fever ceased after an average period of 1.65 days and parasites disappeared after an average of 3.65 days. Similar results were obtained in eight patients treated with 300 mgm paludrine a day for 7 days. A single dose of 100 mgm is amply sufficient to avert the attack.

Nine patients were inoculated with an African strain of *P. malariae* in its 137th passage. They each received 200 mgm paludrine a day for 7 days, the treatment starting from the 4th to the 10th day of fever in 4 cases, from the 10th to the 15th in 4 cases, and on the 24th day of fever in one case. On an average, the fever disappeared in 1.88 days and the parasites after 8.8 days (3 to 14). In only 3 patients did the parasites disappear during the course of the 7 days' treatment. Results similar to these were obtained in 4 patients treated with 600 mgm paludrine a day for 7 days, and in 12 others treated with 600 mgm a day for ten days. *P. malariae* shows a degree of resistance to paludrine comparable to that previously observed to other schizonticidal drugs.

CHAUDHURI, R. N. & CHAKRAVARTI, H. Intravenous "Paludrine" (Proguanil)
Brit Med J 1949, Jan 15, 91-3, 1 fig

Eleven patients suffering from malaria in Calcutta were treated with intravenous injections of paludrine acetate (soluble proguanil). Eight had *P. falciparum*, 2 *P. vivax* and one mixed infections. Most of the patients had serious cerebral or gastro-intestinal complications that rendered their cases unsuitable for medication by mouth. Details are given of each case. At first the dose was 100 to 200 mgm repeated two or three times at intervals of four hours. Later it was a single dose of 300 or 400 mgm. The total amount of paludrine per case injected ranged from 200 to 600 mgm. With the higher doses the blood became clear of parasites in from 24 to 48 hours and the temperature fell to normal in from 32 to 72 hours. One patient in a moribund state died. Another with typical cerebral malaria remained unconscious for several days, developed signs and symptoms of encephalitis but ultimately recovered. The injections were well tolerated. One patient however, had transient phlebitis of the injected vein.

COVELL, G., NICOL, W. D., SHUTE, P. G. & MARYON, M. "Paludrine" (Proguanil) in Prophylaxis and Treatment of Malarial Infections caused by a West African Strain of *P. falciparum*. *Brit Med J* 1949, Jan 15, 88-91.

The authors refer to the very divergent accounts of the efficacy of paludrine in the treatment and prophylaxis of malaria that have emanated from different parts of Africa and elsewhere. To clear up some of the points at issue they undertook a series of prophylactic and therapeutic trials at Horton Hospital, Epsom, using a strain of *P. falciparum* from Lagos, Nigeria. Laboratory-bred *A. stephensi* were used for transmission. Twenty-seven patients were used in the prophylactic tests, they were each infected once a week over a period of six weeks. Drug administration was started three days before the first infection and continued until the sixth day after the last infection. The dosages of paludrine used were 100 mgm daily, 50 mgm daily, 100 mgm twice weekly, 300 mgm once weekly—five patients in each group, together with 7 controls (2 on quinine and 5 on no drug). Paludrine was found to act as a true causal prophylactic against this strain of *P. falciparum*. The prophylactic dose recommended for non-immune adults exposed to malaria infection in West Africa is 100 mgm daily.

Twenty-five other patients were used in the therapeutic tests, the schedules and results are shown in tables, paludrine controlled the clinical attacks in

these patients but its action both as regard the persistence of liver and of parasites in the peripheral blood, was somewhat slower than that of mepacrine or quinine. Paludrine unaided failed to effect radical cure of infection with this strain: this was in marked contrast with the results of FAIRLEY *et al* with New Guinea strains [this *Bulletin* 1947 v 44 282]. Radical cure was apparently obtained with 300 mgm. paludrine twice daily for 10 days plus 800 mgm. of mepacrine given in 3 doses on the first day of treatment (6 cases) (shown in the table as 5) with 300 mgm. paludrine twice daily for 10 days plus 30 grams (2 gm.) quinine hydrochloride given in 3 doses on the first day of treatment (5 cases) and with 10 grains (650 mgm.) of quinine hydrochloride twice daily for 10 days (5 cases).

After a course of 300 mgm. paludrine twice daily for 10 days gametocytes were non-infective to mosquitoes.

A course of paludrine 300 mgm. twice daily for 10 days together with 800 mgm. mepacrine in 3 doses on the first day shortened the duration of clinical symptoms by about 24 hours. Such a course followed by a maintenance course of 100 mgm. paludrine a day for the following six weeks should secure rapid termination of the clinical attack, a high radical cure rate and sterilization of gametocytes with a minimum risk of toxic effects. Norman Macle

BURN, J. H. & VANE, J. R. The Inhibitory Action of Paludrine on the Secretion of Gastric Juice. *Brit. J. Pharmacol. & Chemotherapy* 1948 Dec. v 3, No. 4 348-9 2 figs. [12 refs.]

The increased secretion of gastric juice which occurs in patients with peptic ulcer can also be produced by histamine. During or between periods of intravenous infusion of the latter substance to anaesthetized cat the inhibitory effect of paludrine and related substances on the secretory flow was determined and provided a severe test of such action. The drugs for test were administered in a single intravenous dose or by infusion. Sometimes there was a transitory rise in secretion immediately after administration. Paludrine reduced secretion both as regards volume and amount of free and pepsin. The only other substance with comparable activity was that in which a methyl group replaced the isopropyl group of paludrine. Gastro-intestinal symptoms in man and anorexia in dogs which may arise from administration of paludrine are probably related to the present findings. J. D. Fulton

VANE, J. R., WALKER, J. M. & PARRY, C. B. W. The Effect of Paludrine on Gastric Secretion in Man. *Brit. J. Pharmacol. & Chemotherapy* 1948 Dec. v 3 No. 4 350-51

"1. The effect of paludrine on gastric acidity has been investigated by carrying out test meals on 8 subjects.

"2. A significant reduction in acidity occurred when 0.9-1.0 g. paludrine was given by mouth 2 hours before the test meal.

DOLL, R. & SCHNURDER, R. The Effect of Paludrine on Human Gastric Secretion. *Brit. J. Pharmacol. & Chemotherapy* 1948, Dec. v 3 No. 4 352-3

1.0 g. paludrine hydrochloride given 2 hours before the start of a gruel test meal produced a significant depression of more than 33 per cent in the concentration of free acid during the first 1½ hours of the meal. A consistent effect was observed with doses of up to 400 mg. paludrine acetat given intravenously on the gastric secretion in response to histamine.

- 1 BRITISH MED J 1949, Jan 15, 106-7 Second Thoughts on Proguanil [16 refs]
- 11 COVELL, G Second Thoughts on Proguanil [Correspondence] *Brit Med J* 1949, Jan 29, 192

1 A leading article in the *British Medical Journal* deals with the fact that many new pharmaceuticals in the past quarter of a century have failed to live up to the high reputation that early therapeutic trials had engendered. Paludrine, now known as proguanil, is taken as an example. Reference is made to many discordant results with numerous strains of malaria from different parts of the world, which have recently been published. On the debit side it is stated that complaints have been made of loss of appetite, reduction of weight, and lack of energy from some of those who have taken proguanil for considerable periods. A comparison is made of the effects of mepacrine and proguanil respectively, in the treatment of falciparum malaria in West Africa. "It is thus doubtful whether the ideal drug either for the prophylaxis or radical cure of malignant tertian malaria has yet been discovered."

11 COVELL challenges the assertion that proguanil in doses generally used for prophylaxis or treatment has any adverse effect on the digestive system. One of the outstanding advantages of the drug is due to the extremely wide margin between its effective and toxic dosage, it is particularly suitable for prophylaxis and treatment among indigenous populations of malarious countries. A single-dose treatment of 300 mgm for the clinical attack, and a single weekly dose of 300 mgm for prophylaxis have been widely used in India, Malaya and parts of Africa. Large numbers of British troops have been taking 100 mgm of proguanil a day over extended periods, and no reports suggesting an adverse effect on appetite have yet been forthcoming. Covell examines critically the results of experiments by SCHMIDT *et al* on animals [see below] and of those workers primarily concerned with a drug which might inhibit the secretion of gastric juice in the treatment of chronic peptic ulcer, [above] in support of his arguments relating to the effects of proguanil in the dosages used in man for the prophylaxis of malaria [see COVELL *et al*, above]. "It would be most unfortunate if an impression were to be created, on such slender evidence, that the prophylactic use of proguanil is likely to have an adverse effect on the nutrition of any population to whom it is administered."

SCHMIDT L H, HUGHES, Hettie B & SMITH, C C On the Pharmacology of N_1 -Para-Chlorophenyl- N_6 -Isopropylbiguanide (Paludrine) *J Pharm & Exper Therap* 1947, July, 1, 90, No 3, 233-53, 1 fig [17 refs]

SPINKS & co workers have reported on the estimation, excretion and tissue distribution of paludrine in laboratory animals [this *Bulletin*, 1946, 1, 43, 400-707 1947 1, 44-55]. The present authors have used rats, mice, dogs and monkeys for a pharmacological and physiological study of the same substance. In the mouse continued oral treatment in sublethal doses did not affect growth or general well-being, in the rat effects were slight. Intramuscular dosage was less well tolerated. In animals generally the chief effect of the drug during chronic toxicity tests with a certain dosage was impairment of appetite with consequent effect on growth. No pathological lesions were noted in the tissues of the rat or mouse. Experiments on dogs and monkeys were conducted in similar fashion the drug being administered by stomach tube. The chief toxic symptoms in the dog were salivation, bilious vomiting and loss of appetite. In fatal cases there was marked haemo-concentration with increase in haemoglobin and red cell count whereas white cell counts did not differ significantly from

normal. Intoxicated animals exhibited bradycardia, but again no gross changes were present in the organs. Recovery from the effects of paludrine was rapid when the drug was discontinued, in marked contrast to the results obtained with quinacrine (mepacrine) or chloroquine. For estimation of paludrine the method noted above was used when absorption and tissue distribution was being investigated. When given by stomach tube absorption of the drug was complete but not rapid. Plasma level reached a peak value in 2 hours and declined to zero within 24 hours. The levels attained were generally in proportion to dosage but differences were apparent in different animal species as well as in individuals of the same species. The amounts present in different tissues during chronic toxicity tests varied widely in different organs but there was no tendency for accumulation except perhaps in the liver at the higher doses. In the rat excretion was mainly in the faeces and to a smaller extent in the urine. Some drug was secreted into the bowel partly in bile. The results obtained from estimation of the amount of paludrine in the tissues and excretions suggested that approximately half the drug administered was being metabolized. Comparison of the toxicities produced by paludrine, quinacrine (mepacrine) and chloroquine showed that the first named possessed advantages in that the adverse effects were confined to the gastro-intestinal tracts were readily detected and easily reversed. The drug moreover did not tend to accumulate like the two latter drugs.

CAYET J. Essais de traitement curatif du paludisme aigu par un nouveau dérivé synthétique la Nivaquine C. [Treatment of Acute Malaria with a New Synthetic Derivative, Nivaquine C.] *Bull. Soc. Path. Exot.* 1943 v. 41 Nos. 9/10 534-8.

The author reports the treatment of 120 patients in Cochín (China) suffering from acute malaria with Nivaquine C. Of these patients 101 were agricultural workers, originally from Tonking. *P. falciparum* 91 *P. vivax* 10 14 are Annamite children aged 2 to 13 *P. falciparum* 10 *P. vivax* 4 5 European adults *P. falciparum* 1 *P. vivax* 4. All had been long settled on a rubber plantation in a hyperendemic malarious region. All had suffered from repeated attacks of malaria and all had large spleens. There was no case of primary infection. All had typical acute attacks of malaria—paroxysms attacks and cases of malarial cachexia were excluded from the inquiry.

All patients received 0.3 gm. of Nivaquine C. a day (adult dose) until two successive blood examinations both failed to reveal schizonts, thick drops and smears were examined night and morning. In *P. falciparum* infections 67 per cent. of patients were free from fever on the second day, 80 per cent. were free from fever on the third evening. In *P. vivax* infections fever disappeared somewhat more rapidly. *P. falciparum* schizonts disappeared in 1 per cent. of cases on the third day, in 57 per cent. on the fourth day and in 20 per cent. on the fifth day. *P. vivax* schizonts were somewhat more persistent, 11 per cent. by the fifth day 87 per cent. of patients were parasite-free.

Nivaquine C. appears to be completely ineffective against the gametocytes of *P. falciparum*.

The author concludes that the antimalarial action of Nivaquine C. is identical with that of quinacrine to which it is comparable inasmuch as it is not very low and it does not discolour the skin. The adult dose of 0.3 gm. is sufficient for the treatment of a typical acute attack, doses as high as 1 gm. a day are well tolerated. For grave forms of malaria and permanent attacks, the author still employs intra-cerebral quinone emulsion. (Nivaquine C.)

CIUCA, M, BALIFF, L & CHELARESCO, M, with the co-operation of A TIMISESCO, F VASILIU-MUNTEANU & M V TROFIN Trials of Causal Prophylaxis of Malaria with Paludrine *Bull World Health Organization* 1948, v 1, No 2, 297-300, 3 figs

An old strain of *P. falciparum* used for malaria therapy in Rumania was used in these experiments

Of 5 subjects inoculated with a single dose of sporozoites and given 100 mgm paludrine on the day of inoculation and on the three following days, 2 developed infection after incubation periods of 29 and 35 days, one developed only parasitaemia, the remaining two showed neither fever nor parasites during 57 and 66 days observation, respectively. Of 3 untreated controls one developed a slight infection after 11 days incubation, one an ordinary infection, and the third showed only parasitaemia after a long incubation period.

In a second series, 100 mgm paludrine was continued until the 6th day of the incubation period. Of four patients inoculated with at least 280,000 sporozoites and treated as above, one developed infection after 34 days, and a second parasitaemia after 35 days incubation. The other two developed neither fever nor parasitaemia during observation periods of 23 and 156 days. The dosage in both these series was insufficient to achieve causal prophylaxis.

In a third series, five subjects were inoculated with sporozoites repeated over a period of 4 weeks. They were given 100 mgm paludrine once weekly during this period and two further weeks. They developed fever and parasitaemia 7, 18, 6, 6 and 9 days after the final dose of paludrine. There was no causal prophylaxis.

In a fourth series, 5 subjects were inoculated with sporozoites twice a week over a period of 4 weeks. Paludrine 300 mgm was given once a week during inoculations and continued for a further two weeks. None developed fever and there was no parasitaemia during at least 23 days after final inoculation. Four untreated controls developed the disease after incubation periods of from 12 to 15 days.

DAVIDSON, G "Gammexane" and Mosquito Control in the Belgian Congo *Brit Med J* 1949, Jan 15, 101-2

For the purposes of mosquito control water-dispersible powders containing gammexane have been sprayed on the internal surfaces of African houses in a palm-oil plantation and neighbouring villages in Yalgumba, Belgian Congo, aiming at a concentration of 10 mgm of gammexane per square foot.

Eclipse Works pneumatic sprayers have applied 5 pint of spray per 1,000 square feet of surface.

Results so far indicate a very marked reduction in the number of anopheline mosquitoes caught by four methods —

(a) Pyrethrum in kerosene spray and white sheets on the floor

(b) Window-traps to catch mosquitoes leaving each morning

(c) Mosquito net traps attached to a bed, which show numbers of mosquitoes entering at night to bite occupants of one bed.

(d) The personal calico nets of the inhabitants, acting as traps because of bad state of repair or incomplete closure. This result is expressed as a percentage of nets containing mosquitoes.

The unreliability of estimating the persistence of the insecticide by determining mosquito densities by the bit-catching method alone has been clearly demonstrated. Fifteen or sixteen weeks appears to be the period of maximum effect of the insecticide.

The principal anopheline is *A. monochelis* which breeds at the edges of the large rivers in this tropical forest type of country: a few *A. gambiae* and *A. falcatus* occur. Salivary gland dissections (tabulated) indicate an absence of infected mosquitoes in the treated villages as compared to 0-40 per cent *A. monochelis* and 4-17 per cent *A. gambiae* infections in untreated villages.

For malaria control purposes in this particular area it is thought that an initial spraying of the whole area three times during the first year can be reduced to twice a year.

[This is a preliminary report and will be followed by a more detailed account.]

HEISCH R. B. & WILSON D. O. Preliminary Trial with 5 lb. DDT Smoke Generators against Mosquitoes. *East Afr. M. J.* 1948 Oct. 25 No. 10 400-404.

An endeavour to assess under field conditions the value of DDT smoke as a means of killing adult mosquitoes and larvae at their natural breeding places yielded inconclusive or negative results.

The methods of assessment were by the exposure of adult mosquitoes in cages, the exposure of larvae in bowls and the counting of larvae in the swamp. The numbers of survivors were high and, under the conditions of the experiment the mortality may or may not have been due to DDT.

The authors concluded that the 5 lb. DDT smoke generator is unlikely to be of any value in malaria control in East Africa.

[The result of the analysis of swamp vegetation for DDT deposit is not included.]

R. Ford Trevel

DA COSTA A. M. & BASSÈRES M. S. Ação do DDT sobre o *A. darlingi* e *A. albopictus* e outros Culicídeos. [Action of DDT on *Anopheles darlingi* and *A. albopictus* and other Mosquitoes.] *Rev. Serviço Especial de Saúde Pública* Rio de Janeiro 1948 Mar. v. 1 No. 4 997-1008. 1 graph. English summary.

These experiments were made at Alfredo Maia, Brazil during 1946 and 1947. Weekly collections of anophelines from houses during the previous two years had shown that the number varied between 6.6 to 7.5 per standard collection.

Ten of the houses were then sprayed with DDT in water at 3.5 gm DDT per square metre, ten others at 2.5 gm DDT per square metre, similar groups of houses were treated with 2½ per cent DDT in kerosene at the same rates, seven houses were treated with a pyrethrum insecticide at 2 gm pyrethrum per square metre and ten houses were untreated.

Collections of mosquitoes were made from all houses for twenty-seven weeks after treatment. These captures were separated into *Anopheles darlingi*, *A. albiparvus* and "other mosquitoes". The weekly figures for living and dead mosquitoes taken from each group of houses are given in tables.

The total numbers of mosquitoes found dead in each experimental group are given as —DDT/water at 3.5 gm, 197 (93.8 per cent), DDT/water at 2.5 gm, 72 (93.5 per cent), DDT/kerosene at 3.5 gm, 86 (80.0 per cent), DDT/kerosene at 2.5 gm, 100 (73.0 per cent), pyrethrum, 30 (27.3 per cent) and in the control group of houses, 9 (2.6 per cent). The two concentrations of DDT in water were equally effective. During the last few weeks of the experiment, the number of mosquitoes captured alive in houses treated with DDT in kerosene formed 85.4 per cent of the total number of living mosquitoes found in DDT-treated houses, the authors therefore consider that DDT in water suspension has better lasting qualities than DDT dissolved in kerosene.

DEANE, L M, FREIRE, E P S, TABOSA, W & LEDO, J. A aplicação domiciliar de DDT no controle da malária em localidades da Amazônia. [House Spraying with DDT in Malaria Control in Amazonia] *Rev Serviço Especial de Saúde Pública* Rio de Janeiro 1948, May, v 1, No 4, 1121-61, 9 figs. English summary.

An account is given of a large-scale programme of residual spraying with 5 per cent DDT in kerosene in buildings in the Amazon region of Brazil, having as its ultimate aim the prevention of malaria by the destruction of its vector *Anopheles darlingi*.

The results obtained in 1945 in the small town of Breves were so successful that the treatment was extended to other areas, and by September, 1947, a total of 27 areas, with a population of approximately 33,000, were being treated. At first, the spraying of the houses was done every two months but later a four-month interval was established. Some localities were regarded as experimental areas, but in others the treatment was applied to all buildings (7,303).

The inner surfaces of the walls were sprayed to a height of 3 metres at an average concentration of 2.113 gm DDT per square metre.

A survey in Breves before spraying started, showed that 22 per cent of the blood slides were positive for plasmodia and gave a spleen rate of 45 per cent. In May, 1946, after one year of bi-monthly spraying, these rates were 1.5 and 16.8 per cent respectively, a year later they were 0.3 and 8.3 per cent, respectively. Three months after spraying started, no *A. darlingi* could be found in the houses, and after the sixth month only sporadic cases of malaria occurred. Among children born during this campaign there was no malaria.

In other towns, surveys made before and after DDT treatment, showed that the parasite rate fell from 9.9 to 3.1 per cent and the spleen index from 24.6 to 13.7 per cent. The number of malaria cases was only 43.3 per cent of the number recorded before treatment during a corresponding period, but in untreated localities this figure was 90.9 per cent.

In Manaus, Amapá, Macapá and Mazagão, *A. darlingi* had either become very rare or had completely disappeared from houses.

Methods are described and costs are given, as also are the complete figures for each locality, maps of the areas and samples of the record forms. Photographs show details of the type of equipment used.

H S Leeson

4) out. By estimation of quinine in plasma the authors (this Bulletin, 1943 v. 43-404) have shown that, in contrast to the known facts about antiparasitic drugs, the maintenance of a certain concentration in blood was not necessary for the suppression of *P. lopharii* infections in ducks. Studies by other authors have indicated that in the case of certain infections the same is true of penicillin and streptomycin. The results are of theoretical and practical interest.

J. D. F. n.

BACIGALUPO J. Etapa invisible del *Plasmodium gallinaceum* Brumpt, 1911 (An invisible stage of *Plasmodium gallinaceum*.) *Seminario M.D.* 1947 Dec. 2 v. 55 No. 49 1151-4

The author in 1943 obtained a strain of *P. gallinaceum* and has kept it going. Examination of the plasma of infected birds did not reveal any parasites, nevertheless injection of it did, in some cases, set up infection. The question then arose as to whether the infective material was or was not capable of passing through a filter—the disk sterilizing filter of the Filter Corporation, New York.

The plasma diluted with Ringer's solution and injected intramuscularly caused the signs of infection to appear in 8-18 days whereas when injected similarly after dilution and filtration infection was observed in 25-30 days. Intracerebral inoculation of blood containing parasites might give rise to symptoms as early as 15 hours after or as late as 4 days.

The author discusses the possible implications of these results.

LEWERY R. M. Exoerythrocytic Infection by *Plasmodium gallinaceum* in Blood-Infected, Quinine-Treated Chicks with special reference to the Central Nervous System. *Amer. J. Hyg.* 1948 Sept. v. 48 No. 3, 194-208 coloured figs. on 1 pl. [13 refs.]

An account is given of the sites of invasion in the tissues of the chick, treated with quinine by the exoerythrocytic forms of *Plasmodium gallinaceum* with special reference to the forms seen in the brain. The infections were produced by blood inoculation and the results of the experiment may be summarized shortly—

- All parts of the brain were invaded by exoerythrocytic parasites.
- Although the intensity of the infections varied in individual there was a general agreement with regard to the parts of the brain most highly parasitized. The difference in parasite density appeared to be directly related to the richness of the capillary circulation, the parasitism being greatest where the capillaries were most numerous and especially where they were relatively unbranched.
- The quinine therapy suppressed the primary parasitaemia but when the exoerythrocytic density became great, young ring forms of the erythrocytic series, unaccompanied by older forms were able to invade the erythrocytes.
- Blocking of the capillaries is due both to swollen parasitized endothelial cells of the capillaries and to free embolic schizonts.
- Stickiness of the capillary endothelium developed only after the establishment of the infection in the capillaries.
- The endothelium of the brain capillaries is invaded before that in other organs and tissues.

HAWKING, F. & PERRY W. L. M. Activation of Paludrine. *Br. J. Parasitol. & Chemotherapy* 1948 Dec. v. 43 220-25 1 fig.

It was found by TONKIN (this Bulletin 1947 v. 44 184) that paludrine was inactive against the exoerythrocytic forms of *P. gallinaceum* in vitro. In vivo

of the *in vivo* activity it was concluded from preliminary experiments [*ibid.*, 1947, v 44, 648] that the drug was activated by host cells. Further evidence of this activation is now given. Sterilization of cultures was obtained by addition of serum from a fowl treated with paludrine, but none if the drug was added directly unless it were added in a concentration toxic to the cells themselves. LEVADITI and YAMANOCHI (*C R Soc Biol*, 1908, v 65, 23) showed that incubation of atoxyl with rabbit liver rendered this substance active against trypanosomes *in vitro*. Paludrine has been found to be activated by using rat liver. Calculation showed that only a very small amount of the active material formed could have been present in the cultures. ACHESON *et al* [this *Bulletin*, 1947, v 44, 964] have shown that the active substance is probably not a benzimidazole derivative derivable from paludrine itself. Experiments with the monkey parasite *P. cynomolgi* gave similar results to the above. The authors concluded that paludrine itself is probably not the active antimalarial agent but rather some substance derived from it by the action of body cells. This substance was not bound to protein and was stable at 100°C. J. D. Fulton

MICKS, D. W., DE CAIRES, P. F. & FRANCO, L. B. The Relationship of Exflagellation in Avian Plasmodia to pH and Immunity in the Mosquito. *Amer J Hyg* 1948, Sept., v 48 No 2, 182-90, 1 fig [16 refs.]

The study which is the subject of this paper was undertaken to investigate the factors underlying the inability of certain species of mosquitoes to act as hosts for various avian malaria parasites, especially *Plasmodium elongatum*. The other species used were *P. cathemerium* and *P. relictum*, while the mosquito species investigated were *Culex pipiens*, *C. quinquefasciatus* [*C. fatigans*], *Aedes aegypti* and *Anopheles quadrimaculatus*.

Exflagellation preparations were made in two ways and observed at room temperature. In the first method, a drop of bird's blood was mixed with a drop of isotonic saline-citrate solution and the mixture sealed under a coverslip. In the second, the last two abdominal segments were cut off a mosquito immediately after it had fed, the blood was expressed on to a slide and sealed as before.

On the assumption that the hydrogen-ion concentration in the gut might be the important factor concerned in the varying susceptibility of mosquitoes to infection, the pH values of the contents of mosquitoes' stomachs were investigated. The Beckman pH meter was used and the pH values of the stomach contents of both unfed and fed mosquitoes were determined.

In the case of *P. elongatum*, it was noted that exflagellation did not take place in preparations made from the bird's blood but took place readily and rapidly in the contents of the mosquitoes' stomach (*C. pipiens*). On the other hand, such exflagellation did not take place when the mosquitoes used were *Aedes aegypti* and *A. quadrimaculatus*. This seemed to indicate the presence of some factor in the stomach of *C. pipiens* which provoked exflagellation.

It is unnecessary to describe the various other experiments carried out with the species of *Plasmodium* and mosquitoes previously mentioned but a summary of the conclusions arrived at may be given—

1. No correlation could be shown between exflagellation and pH values.
2. The insusceptibility of a mosquito to infection can manifest itself sufficiently early to prevent even exflagellation.
3. Some chemical factor provoking exflagellation and fertilization of *P. relictum* is present in the stomach of *C. pipiens*.
4. In the stomachs of *Aedes aegypti* and *A. quadrimaculatus* a factor inhibiting exflagellation of *P. relictum* is present.
5. The stimulating factor in *C. pipiens* is activated by the ingestion of blood.

BLACKWATER FEVER

RAOULT A. E. du traitement de la fièvre bilieuse hémoglobinurique par Neo-Antergan. [Treatment of Haemoglobinuric Fever with Neo-Antergan. *Bull. MEd de l'Afrique Occidentale Fr* 1947 v 4 No. 2, 1944]

The use of a synthetic anti-histamine preparation, such as neo-antergan, in the treatment of haemoglobinuric fever was suggested by the analogy between the sudden onset of haemoglobinuria and of other grave complications of malarial attacks, and histamine shock. The author believes that a discharge of histamine is directly responsible for the haemolysis, the natural antihistamine defence of the body being defective, the liver ceasing to play its neutralising rôle.

A child 8 years of age, infected with *P. falciparum* developed rhythmic febrile attacks of haemoglobinuria. The usual treatments including quinine, antivenene, calcium, biocholone and blood transfusions had failed to arrest the attacks and the progressive anaemia. The child was then given 0.5 gm. of quinofilm intramuscularly and 3 tablets of neo-antergan by mouth, at intervals of two hours. The quinofilm was continued for 3 more days and the neo-antergan, 3 tablets a day for a week. Suppression of both haemoglobinuria and albuminuria followed promptly the administration of neo-antergan.

To overcome the difficulty experienced in giving drugs by mouth to patients with haemoglobinuric fever a preparation of neo-antergan suitable for intramuscular injection was prepared for the author. He treated 3 other cases similar to the first by intramuscular injections of neo-antergan and quinacrine. In all cases the haemoglobinuria responded promptly to the medication. The subsequent administration of quinine produced no unfavorable results.

TRYPANOSOMIASIS

JACKSON C. H. \ Some Further Isolated Generations of Tsetse Flies. *Bull. Entom. Res.* 1948, Dec. v 39 Pt. 3 411-51

Further experiments are reported [see this *Bulletin* 1948 43 31*] in which tsetse flies are liberated in an area in which they do not naturally occur and studies made on age, reproduction etc. under these conditions.

The area chosen for an experiment is judged to be not unsuited to the liberated species, which is therefore living under almost natural conditions. As liberation is from pupae and is limited to three days, the age of any fly which is subsequently recaptured is known. The distance it has moved from the point of liberation can also be studied. In each experiment tsetse were liberated in a place in which there is already a closely related native species, thus *G. morsitans* and *g. swinhoei* were liberated in one another's haunts. The general condition of the native community gives a general indication of what the introduced species will encounter.

In the four experiments here discussed (in which *morsitans* and *g. morsitans* were the introduced species) the author compares these flies, using physiological criteria, with others in their native haunts. He also studies their gradual

disappearance, and finds fresh evidence that the males are rather inactive for the first four weeks of life. This modifies previous calculations on length of life in nature, and estimates of population. It seems that the wear and tear of the wing ("wing fray") proceeds at much the same rate at different seasons, so that it may develop into a means of measuring the mean age of groups of tsetse. Unusually small flies, perhaps the smallest 10 per cent, seldom live long enough to take a meal of blood. Size of offspring depends on the mother's nutrition during pregnancy, it follows that some apparently minor unfavourable factor might have a marked effect on the numbers in a population of tsetse.

The three larval instars are distinguished, and identified in recaptured specimens of the introduced species, of which the age is known, as explained above. At a screen temperature of 24°C a large larva has been found in the uterus on the 23rd day. There seemed to be considerable irregularity in the commencement of breeding, but perhaps this was due to the experimental conditions. The first flies of the second generation were captured (soft and unfed) on the 53rd day.

MOGGRIDGE, J Y Night Activity of Tsetse (*Glossina*) on the Kenya Coast
Proc Roy Entom Soc London Ser A Gen Entom 1948, Dec 28,
v 23, Pts 10/12, 87-92

The author has made observations on the adult of *Glossina austeni*, a species which is normally regarded as seldom biting man. He finds that on the Kenya Coast, and especially in the dry season, this insect bites man readily at night. Considerable numbers were caught by a party moving along a path in the bush after midnight carrying no lights. As the insects bite irrespective of the state of the moon and are prepared to do so on a very dark night, the view that their sense of smell is important in finding a host is to some extent strengthened. As soon as day breaks, the attack of these insects on man ceases, except that in very dry weather there is a period of "rush activity" they then attack man fiercely for a brief period in the very early morning.

LAUNOY, L Prophylaxie chimique par voie orale, chez le rat, de l'infection expérimentale à *Trypanosoma gambiense* (souche Yaoundé) [Chemo-prophylaxis by the Oral Route against the Yaounde strain of *T. gambiense* in the Rat] *Bull Soc Path Exot* 1948, v 41, Nos 7/8, 464-70, 4 figs on 2 pls

This contribution covers the same ground, with some slight differences of detail, as a recent paper under almost an identical title by the same author [LAUNOY, this *Bulletin*, 1948, v 45, 1071]

An interesting point mentioned in the present report is that the strain of *T. gambiense* used has retained its infectivity for man after being maintained in laboratory animals for 14 years, as proved by an accidental human infection in Paris in December 1947.

DEWEY, H M & WORMALL, A Studies on Suramin (Antrypol, Bayer 205)
6 Further Observations on the Determination of Suramin in Whole Blood and Serum *Biochem J* 1948, v 43, No 1, 24-7 [12 refs]

Simple methods for the estimation of suramin (Antrypol, Bayer 205) in serum and plasma, by means of acid hydrolysis followed by diazotization, have already been described [this *Bulletin*, 1938, v 35, 714, 1939, v 36, 668]. In view of the possibility of bacterial contamination in specimens

kept for some time and subsequent production of substances which would vitiate the result of the colorimetric estimations the effect of addition of various antiseptics to the test specimens has been investigated. In the case of oxalated and defibrinated whole blood or of washed red cells the recoveries of added suramin in contrast to those with plasma or serum, were low and variable when hydrolysis was carried out for the usual 6 hours and were not improved by increasing the reaction time. Some constituent of the red cells, or product derived from them, is apparently responsible for the low results obtained. If however hydrolysis in those cases is carried out before the addition of suramin satisfactory results are obtained. The amount of suramin which combines with red cells when added to whole blood or as a result of injection in animals is negligible. The addition of 0.2 ml. of 5 per cent. (w/v) phenol or half that amount of 0.5 per cent. merthiolate added to 2 or 3 ml. of plasma or serum did not interfere with satisfactory recoveries of suramin.

J. D. Fulton

GALE J. C., ROSE F. L. & SCOTT MARY. The Estimation of Suramin in Plasma. *Biochem. J.* 1948, v. 42, No. 4, 574-72 figs.

Methods for the estimation of suramin (Bayer 203 Antrypol) have been described in which the acid or alkaline fission products are converted to an azo dye [this *Bulletin* 1933, v. 35, 714; 1943, v. 45, 772]. In the present investigation a method for estimating suramin in aqueous solution, plasma or serum is described, which depends on the colour change produced when the drug is added to a styrylquinoline dye (SQ34). Plasma proteins do not interfere with the formation of the dye complex and the estimation depends on a comparison of optical densities in a Coleman spectrophotometer or a Spekker absorptiometer. The values obtained are referred to a standard curve constructed with known amounts of suramin. The method was compared with that employing the acid hydrolysis referred to above and is claimed to have equal precision and slightly greater sensitivity. It also proved simpler and less time-consuming and should have advantages in field work. A number of possible hydrolysis products were also estimated by the newer method. It was found that only certain types took part in the formation of the coloured complex and showed a correlation with the time of persistence in the blood.

VAN HOOF L., HENRAED, C. & PHIL, E. Quelques observations sur les trypanosomes des grands mammifères au Congo Belge (Observations on Trypanosomiasis in Large Mammals in the Belgian Congo; *Acta Tropica*, 1943, v. 5, No. 4, 327-44 [13 refs.])

(1) CORD F. H. S. & DAVEY D. G. "Antrycide": a New Trypanocidal Drug. *Nature* 1949 Jan. 15, 89-90.

(2) *Nature*, 1949 Jan. 15, 77-8. Sleeping Sickness and Nagana.

(3) "Antrycide" gives promise of a remarkable degree of activity against *T. congolense* besides being highly active also against trypanosome species which are normally more amenable than *T. congolense* to chemotherapeutic treatment.

The name Antrycide is applicable to the various salts of a bis-quaternary base whose formula is given, in which substituted pyrimidine and quinoline rings are connected by an imino linkage.

The following results are given for therapeutic tests in mice with one of the "Antrycide" salts (doses per kgm body weight, subcutaneously) —

<i>T rhodesiense</i> (Tinde)	25 to 5 mgm inclusive, curative Lower doses not quoted
<i>T brucei</i> (Liverpool)	5 mgm, some cures 2.5 mgm, blood temporarily cleared
<i>T congolense</i> (Busumbi)	1.0 mgm, curative 0.5 mgm, some cures 0.25 mgm, blood temporarily cleared 0.125 mgm, blood sometimes temporarily cleared
<i>T evansi</i> (India)	1.25 mgm, curative 0.5 mgm, some cures
<i>T evansi</i> (Sudan)	2.5 and 1.25 mgm, some cures 0.5 mgm, blood temporarily cleared
<i>T equiperdum</i>	0.5 mgm, curative 0.25 mgm, some cures
<i>T equinum</i>	1.25 mgm, curative 0.5 mgm, some cures

Considerable prophylactic action was demonstrated in mice, rats and rabbits. Thus, 12.5 mgm per kgm body weight completely protected mice against *T congolense* (Busumbi) inoculated 28 days later.

In trials now proceeding in Africa, single doses of "Antrycide" salts have already produced cures of *T congolense*, *T vivax* and *T brucei* infections in cattle, of *T brucei* in horses, donkeys and dogs, and of *T evansi* in camels. Considerable protective power has also been demonstrated against *T congolense* and *T vivax* infection in cattle.

(u) This leading article was inspired by the discovery of "Antrycide", referred to in the abstract above. The first public announcement of "Antrycide" was made at a Press conference held jointly by the Colonial Office and Imperial Chemical Industries, Ltd on December 29, 1948.

The article refers to the severe limitations which tsetse flies have imposed on the development of tropical Africa. Mention is made of some of the methods now in use for controlling trypanosomiasis in man and animals, either by measures directed essentially against the fly or against the trypanosome, and the large measure of success already achieved is acknowledged. "There are some hundreds of thousands of people, and their cattle, living where they could not have lived before. Still larger numbers have been protected from sleeping sickness by the use of drugs, and now that it is possible to treat cattle themselves, an even larger area will be available for development." A warning is nevertheless sounded against the expectation of producing any immediate and widespread improvements in food-production or human settlement, in view of technical difficulties of dealing with large numbers of cattle which have never been handled and which range over large unfenced areas.

Mention is rightly made of the other important advance of recent years in the chemotherapy of *T congolense*, namely the introduction of phenanthridinium compounds, culminating in "Dimidium bromide", [reports on which have been conflicting, and the relative value of which has accordingly not yet been finally established]

E M Lourié

GANAPATI, P. N. Cultivation of *Trypanosoma cruzi* in the Developing Chick Embryo [Correspondence] *Nature* 1948, Dec 18, 963-4, 2 figs

Tissue culture of *Trypanosoma cruzi* in the embryonic tissues of the chick is readily carried out, but attempts to cultivate this parasite in the chick embryo itself have been less successful. The account given in this note records the

successful cultivation of *T. cruzi* on the chorioallantoic membrane of the chick embryo both blood forms and cultural forms were used as the inoculum.

The eggs were used after 10-14 days incubation and the inoculation was made by the standard technique of Beveridge and Burnet. The eggs were opened from the third day onwards. All the chicks died before hatching.

The lesions on the chorioallantoic membrane were whitish opaque patches. Sections showed that the infection was in the ectodermal layer which contained numerous "cyts" enclosing large numbers of *T. cruzi* in all stages of multiplication. The mesodermal layer is not involved. *H. E. Shaw*

PIZZI T. & ALLS J. & FLORENZANO R. Estudio preliminar sobre la cardiopatía chagásica en la zona central de Chile. [Preliminary Study of Cardiopathy in American Trypanosomiasis in Central Chile.] *Rev. Med. Chile* 1949 June v 78 No. 6 315-23

The authors examined 411 patients proved by xenodiagnosis to be suffering from Chagas's disease. 397 electrocardiograms were made and 43 showed definite departures from the normal. Among 86 controls four showed abnormalities: one with blocking of the left ramus (with hypertension and cardiac insufficiency) others were slight alterations in the ST segment and the T-wave. The authors conclude that myocardial affections in this disease are neither common nor severe in the zones investigated; the most important are A-V block, especially of the right ramus.

As the authors agree, the study is not very complete because they had no portable X-ray apparatus, nor could they make electrocardiograms on all the patients; on the other hand, controls were few in number, only 86, and they could not be certain that none of them was infected with the disease since they lived in the same districts as the positive (rather serious drawback to the validity of the conclusions). *H. Harold Scott*

LEISHMANIASIS

BAIKEMANN E. Kala-Azar bei einem Holzknecht. [Kala Azar in a Repairman.] *Dtsch. med. Woch.* 1948 Aug. 13, v 73, No. 29-31, 248.

A case in an ex-prisoner of war from Turkey.

BOZZO A. & CANU G. Su un caso di sepsi letale da paratifo A in soggetto con leishmaniosi viscerale. [A Case of Subacute Bacterial Endocarditis associated with Kala Azar.] *Atti Vel. Italiana* 1948, Nov. v 3, No. 11 381-5 1 chart. (14 refs.)

The English summary appended to the paper is as follows:—

"A case of subacute bacterial endocarditis caused by *Salmonella paratyphi A* in a patient with kala-azar has been presented. The authors call attention to the rarity of this aetiology and to the association of subacute bacterial endocarditis with leishmaniasis.

TRAVASSO B. Lo kala-azar su Dodécandee. Foyers et observations. [Kala Azar in the Dodécandee.] *J. Roy. Egyptian Med. Ass.* 1948 Oct. 31 v 10 257-8 (Recd. 12 Dec. 1948)

Two cases from India and one from Africa, occurring in U.S. ex-servicemen.

CHUNG, Hui-lan, CHOW, Hua-k'ang & LU, Jui-ping The First Two Cases of Transfusion Kala-Azar *Chinese Med J* Shanghai 1948, June, v 66, No 6, 325-6 [10 refs]

This paper describes the apparent transmission of kala azar to two children by blood transfusion from a mother suffering from the disease. On diagnosis of the mother's condition, made after the transfusions, a close watch was kept on the two children. Kala azar was diagnosed in each after the lapse of nine and ten months respectively.

[There is no reason to doubt that the most probable cause of the disease in the two children was the blood transfusion, since *Leishmania donovani* is constantly present in the blood of untreated cases. None the less, the possibility of transmission by *Phlebotomus* flies from mother to child cannot be excluded in spite of the recorded fact that the premises were "well screened against insects as it was occupied by a well-known parasitologist." After all, the mother had acquired the infection without blood transfusion.] *H E Shortt*

DANA, R, CORCOS, A & SEBAG, A Deux cas de kala-azar chez un adulte et chez un enfant guéris par le 2168 R P [Glucantime] [Two Cases of Kala Azar, an Adult and a Child, cured by Glucantime (2168 R P)] *Bull et Mém Soc Méd Hôpit de Paris* 1948, Nos 20/21, 644-8, 2 charts

Two cases of kala azar are reported. One a young woman aged 27 years from Tunisia, complained of fever with rigors and sweating, weakness, and loss of appetite of about 6 months' duration. Her spleen was four fingers' breadth below the costal margin and the liver was enlarged. *Plasmodium vivax* schizonts were found in the blood. Anti-malarial treatment brought down the temperature for about 8 days, but the fever returned and on this occasion *P falciparum* parasites were found. Despite further anti-malarial treatment, irregular fever persisted, the spleen now reached to the crest of the ilium, and the liver was four fingers' breadth below the costal margin. The inguinal and axillary lymphatic glands were enlarged. Leishmaniae were found on sternal puncture. The leucocyte count was 630 per cmm and the haemoglobin 32 per cent.

The patient was treated by "glucantime" (2168 R P) intramuscularly, in 15 doses, 5, 5, 6, 8, 10 × 8, and 12 × 3 ml = 140 ml (=11.30 grammes of antimony), on alternate days. The temperature fell after the second injection. After this course the spleen and liver were reduced to less than half their previous size and the blood picture improved (haemoglobin 58 per cent). Control sternal puncture was refused, but over 3 months later the patient was reported to be in excellent health with no return to fever.

The second case was in a child of 5 years from Beja (Tunisia), with an oscillating temperature (37.5° to 39°C), anaemia (62 per cent haemoglobin), leucopenia (2,100 per cmm), a large spleen reaching almost to the iliac crest, and an enlarged liver. Leishmaniae were found on sternal puncture. The same drug was given in 15 doses of 2.5, 4, 5 × 4, and 6 × 9 ml = 75 ml [*sic* ? 80.5 ml] corresponding to 19.50 grammes of the product (presumably a 25 per cent solution). The temperature fell and remained below 37°C after the 4th injection, the spleen and liver were reduced, and the leucocyte count rose to 5,500 per cmm after one month. Sternal puncture was now negative. The child, still in excellent condition, was readmitted after three weeks and given a second similar course of 15 injections totalling 88 ml.

The authors emphasize (i) the danger of overlooking kala azar in patients with malaria especially when the splenomegaly persists after the temperature has fallen and (ii) the excellent results they obtained with glucantime (2168 R P).

[There is no information on the formula of 2168 R.P. but from its dosage and antimony content it might be identical with sodium antimony glucosate

Ho E. A. Hsu Tze-hui & Li Y. A Report on Examination of 994 Dogs in Shan and Its Nearby Villages for Leishmaniasis. *Chinese Med J Shanghai* 1948 July v 66, No 7 337-9 [11 refs.]

"Four of 483 dogs examined in Shan were found to have visceral leishmaniasis with cutaneous manifestation, but among 506 dogs examined in 47 nearby villages none showed the infection."

CARLEONI G. Contributo allo studio della leishmaniosi cutanea. [Cutaneous Leishmaniasis.] *Giorn di Med Milit.* 1948, Mar-Apr., v 83 No 2, 127-9

Much has been compressed into a small space in this concentrated account of the treatment of cases of cutaneous leishmaniasis. The figures throughout are given as percentages—a little inclined to mislead when the total dealt with were 31, 29 and 25 in different parts of the contribution.

Of the 31 Italian prisoners of war under the author's care and suffering from oriental sore, 23 came from the Province of Gondar, 4 from Cyrenaica and each from Eritrea and Asmara [stated as 75 per cent. of cases coming from Gondar Province]. There was none from Somalia or southern Ethiopia. The incubation period, i.e. the time between leaving the infective area and the appearance of symptoms, was 2-5 months in 24 per cent., 7 or 8 patients; 7-12 months in 32 per cent. [10?]; 13-4 months in 24 per cent., 24-36 months in 16 per cent., over 36 months in 4 per cent. [1 or 2?]; the longest period was one of 57 months.

Several methods of treatment were tried: trivalent antimony intravenously and intramuscularly with formalin and antihomaline; pentavalent stibocin intramuscularly; stilbenylurea intravenously; all without benefit. Local infiltration with antihomaline was equally ineffectual. In 4 patients good results were obtained with antimony ointment or urea-antimony 2 per cent., cure resulting in 60, 62, 90 and 30 days. Local injections of emetine proved very serviceable, but it cannot be used near the eyes as it set up a violent conjunctivitis. Atebrin [mepacrine] injections brought about cure in a month and a half in 4 patients with oriental sores ranging in size from that of a chickpea to a kidney bean. Those in whom the lesion was extensive, ulcerated and lupoid were more resistant. Of 25 such 10, stated as 40 per cent., were cured in 45-80 days; 4 [16 per cent.] in 80-110 days; 5 apparently cured relapsed, but were definitely cured by a second course of the atebrin injections. Resistance to atebrin treatment is ascribed to local conditions, because in the same patient one sore might rapidly clear up while another would again and again relapse. In the remaining 6 relapse persisted in spite of repeated injections. In 4 of these satisfactory results followed the application of sulphamide in powder after cleaning and deep scraping of the ulcer. The powder was applied at first every day, then every second, third and fourth day. [no other details are given] cure was obtained in 29, 30, 30 and 45 days. H. Harold Scott

PÉREZ CHAVARRIA, A. GUARES ARIAS, J. C. ROMERO LÓPEZ, A. I. ULLI, J. H. M. & CASTRO JENKINS, A. Leishmaniasis tegumentaria en Costa Rica. Se propone una clasificación dermatológica de la leishmaniasis tegumentaria. [Cutaneous Leishmaniasis in Costa Rica. A Proposed Classification according to the Skin Lesions. *Rev Med Cost Ric* 1948 July-Dec., 7 No 147/15, 66-97, 4 figs & 1 map, 89 ref.]

Cutaneous leishmaniasis is endemic in Costa Rica—cases can be seen at all seasons but increase in number with the wet season and mostly at the levels

of some 700 metres above sea-level *Phlebotomus* abounds in all the affected regions

In this article, 100 cases are analysed 54 from the Province of Limon, 20 from Alajuela, 16 from San José, 5 from Guanacaste, 2 each from Cartago and Puntarenas and one from Heredia As regards sex, the authors state that men are more attacked than women [but no other reference is made to the sex and a tabular statement gives "86 males, 84 females," an obvious mistake in a total of 100 patients] Clinical forms are divided into 1, those with rupial ulcers (*ulcero-costrosas*), much the most numerous (84), 2, vegetating and rupial (7), 3, affecting the legs only (5), 4, vegetating lesions only (3), raised papule (*botón*) (1) [Not a very satisfying classification There are other errors in the table than that referred to above In the table, analysing 100 cases is the statement, giving the ages "Children under 1 year, 18, to 10 years, 4, and 10 to 80 years, 96, a total of 118] H Harold Scott

PESSOA, S B & VILLELA, F F Estudos sobre o tratamento da leishmaniose tegumentar americana pelo eparseno [On the Treatment of American Cutaneous Leishmaniasis by Eparseno] *Hospital* Rio de Janeiro 1948, Oct, v 34, No 4, 527-32

Eparseno (dioxy-diamido-arsenobenzol) is put up in 1 cc ampoules each containing 0.12 gm of amino-arseno-phenol and is given intravenously In 1926, Pupo reported the results of its use in muco-cutaneous leishmaniasis [see this *Bulletin*, 1926, v 23, 586] It has usually been given at 2-3-day intervals for adults, in a series of 10-15 ampoules, repeating the course after an interval of 10-15 days and so on until 40-50 ampoules, or 4.8-6 gm of the salt have been given

In the present communication, the authors report having tried two methods In the one they give increasing doses beginning with one ampoule, then increasing at two-day intervals to 2, 3, 4 and in one case 5 ampoules for a single dose, with a resting period of 3-5 days after the third or fourth injection For example, one patient received on January 4th 1 cc, January 6th 1 cc, January 8th 2 cc, January 12th 2 cc, January 17th 3 cc, January 22nd 3 cc, then a rest for 10 days [so stated, but the dates would show a rest for 13 days] February 4th 3 cc and the same dose on the 6th, 8th, 11th, 15th, 18th and 22nd, altogether 33 ampoules or 3.96 gm of the salt

Of 15 patients so treated, six showed toxic signs, four of them severe, but cicatrization occurred, two relapsed

By the other method the dose was kept constant at 1 cc, but injections were made daily for 10 days, then after an interval of 10-15 days a repeat and so on until 40-50 ampoules had been given Eight patients were treated in this way Six were cured, a seventh relapsed 8 months later, in the other cicatrization was incomplete and the treatment was changed for antimony None showed any signs of intoxication and the authors consequently regard the second plan—daily administration of the constant dose—as the better H Harold Scott

FEVERS OF THE TYPHUS GROUP

ERZİN, N İkinci dünya savaşı yıllarında yurdumuzun tifus durumu [Typhus Fever in Turkey in Years of World War II] *Türk İhtiyar ve Tıbbi Biyoloji Dergisi* Ankara 1948, v 8, No 3, 5-9, 1 chart English summary 10-12

An epidemic of typhus occurred in Turkey in 1942 and reached its peak in 1943-44 A reduction in the number of cases to pre-war level did not occur until 1947

The average incidence and mortality in the 10 years before the war (1928-1938) the 4 years up to 1942 and from 1943 to 1947 are shown in a series of tables.

The average number of cases in the 10-year period 1928-1938 was 711 in 1939-1942, 759 and from 1943 to 1947 the actual numbers were 414, 231, 265, 1498 and 641.

It is shown that most of the cases occurred between January and May and particularly in March. This is attributed by the author to lack of communications, which limits the spread of the disease in the winter months.

The incidence of typhus and death rates per 100,000 for different periods were as follows —

Incidence			Death rate	
	Number	Average per 100,000	Number	Average per 100,000
1935-39	475 (yearly average)	2.9	58 (yearly average)	0.3
1940-44	003	11	189	1.0
1945	2,634	13.8	139	0.7
1946	1,498	7.8	103	0.5
1947	641	3.4	58	0.3

The fall in incidence from 1944 onwards is attributed largely to mass vaccination and the use of DDT. Mass vaccination was begun in 1943 and another table shows that the mortality rate from typhus fell from 14.1 in 1942 to 5.0 in 1945 (but rose to 6.8 and 9.0 in the next two years). The incidence of typhus as a percentage of other common infectious diseases rose from an average of about 4 between 1935 and 1942 to about 14 between 1943 and 1946.

H. J. O'D. Burke-G. *Nov.*

FERRO-LUZZI G. Studio sulle malattie del gruppo del dermatite in Eritrea. (*Studies of the Fevers of the Typhus Group in Eritrea.*) *Boll. Soc. Ital. di Med. e Ig. Trop. (Ser. Eritrea)* 1948, v. 8, No. 3, 4, 110-45 9 figs. (7 on 4 pls.) (57 refs.) English summary.

The author gives an interesting summary of the numerous observations made by various Italian workers on the fevers of the typhus group in Eritrea. During the 10-year period 1927-1936, the total number of cases treated at the Asmara Hospital was 37 of which 28 were in Europeans. In 1937 the number of European patients admitted suddenly rose to 35 and in 1938, 24 European and 23 African patients were admitted.

The progress of the epidemic from 1939 onward can be judged from the following figures of admissions of African patients: the fatality rates for all patients for each year are given in brackets.

In 1939 there were 152 cases (14.8%). In 1940 66 (9.8%) and in 1941 320 (14.8%). The admissions rapidly fell to 39 (2.7%) in 1943 and again rose to 1,084 (11.6%) in 1946. The figure for 1947 was 335 (5.1%).

In the years of high prevalence the disease was predominantly of the epidemic type but murine typhus was in evidence throughout the period. Tick-borne typhus was relatively negligible in incidence: the author is inclined to regard all the cases as having been of the *hondanense* type though he states that other workers believe that some of them were of the tick-bite fever type. He describes the chief features of the tick-borne fever as including the occurrence of a tick fever and a papulo-nodular rash which is rare, haemorrhagic and

which extends to the palms, soles and face, the Weil-Felix reaction is inconstant or delayed, and the titres of agglutination of *Pr OX19* or *Pr OX2* are low

In the section dealing with treatment, the author repeats his claim that aspirin in daily quantities of 6-8 gm, continued till defervescence, has caused a fall in fatalities from 14.8 per cent to 1.0 per cent. In a footnote he takes strong exception to the suggestion by the present reviewer that his methods of control may not have been satisfactory and renews his assertion that when cases were selected the more severe were chosen for the trials of the drug [See this *Bulletin*, 1948, v 45, 249]. [One of the present reviewer's comments can now be withdrawn, this was "it also appears that the same group of patients formed the controls for tests of aspirin and three other drugs" This was based on the fact that exactly the same fatality rate was given for the controls of all the four drugs, but it is now explained that really there were four sets of controls and that the fatality rates were so uniform that an average figure was adopted for convenience. The other comments still seem to the reviewer to have been justified by the facts as stated, they were not intended to throw doubts on the good faith of the author and in any case they are now rendered obsolete by the further evidence supplied in the present paper, which follows]

In a further set of trials of aspirin between January 1st and June 30th, 1947, the fatality rate among 74 treated patients was 5.4 per cent and among 112 controls it was 10.7 per cent. These figures are in striking contrast to those given for the earlier trials in which the corresponding fatality rates were 1.0 per cent and 14.8 per cent. In the second half of 1947, the fatality rate among 221 treated patients was only 2.26 per cent, there were no controls. It would seem reasonable to suggest that there may have been a decline in the severity of the disease during the second half of 1947.

The author makes the interesting suggestion that the action of aspirin may be associated with the benzoic radical which is, perhaps, related to that of para-aminobenzoic acid

John W D Megaw

DREGUSS, M & FARKAS, E. Complement-Fixation Test for Serological Studies in Typhus Fever. *Arch f d Gesamte Virusforschung* Vienna 1948, June 30, v 4, No 1, 47-54 [12 refs]

This paper describes work carried out in 1944 when the authors had no access to the reports of similar investigations carried out by BENGTON, TOPPING, FULTON, and other workers.

Among 36 sera of healthy or syphilitic persons there was no case of a positive reaction with the complement-fixation or Weil-Felix tests.

Among 110 sera of patients believed or suspected to have attacks of typhus or typhoid fever there was a general agreement between the results of the two tests, but 13 sera were negative with the Weil-Felix test and positive with the complement-fixation test at titres of 1-16 or over, in 8 of these cases, later examinations were made and high-titre Weil-Felix reactions were observed.

In 4 cases there was a positive Weil-Felix reaction and an absence of complement-fixing antibodies, in these the former reaction "seems to be unspecific", the final diagnosis in two was typhoid fever, in the other two there was no change in the Weil-Felix titres of later samples.

From the results of a number of tests, including those carried out repeatedly on eight patients, the authors conclude that the complement-fixation reaction becomes positive about two days earlier than the Weil-Felix reaction [they seem to have regarded fixation titres of 1-16 as positive and Weil-Felix titres below 1-100 as negative]

In a group of 10 persons the rise in titre resulting from vaccination was more pronounced with the fixation test than with the Weil-Felix test in 2, but two cases.

DREIGUS, M. & FARKAS E. Estimation of the Antigenic Value of Typhus Vaccines by Complement-Fixation Tests. *Arch. f. d. Gesamte Bakt. u. Infektionskrankh.* Vienna. 1943, June 30 v 4 No. 1 85-82.

This paper like the preceding one was greatly delayed in publication. The studies described were carried out in 1944-45.

The complement-fixation test as performed by the authors was found reliable as a means of estimating the immunising value of typhus vaccines.

Among 13 vaccines of various kinds and from different sources only 3 were found satisfactory. Three of these were of the yolk-sac type: one was a mouse-lung vaccine and the fifth was a Weigl house vaccine. One of the yolk-sac vaccines and the Weigl vaccine were prepared in Hungary; the other two yolk-sac vaccines were of American origin and were the only samples obtained from that source.

Among the eight unsatisfactory vaccines five were of the yolk-sac type; the other three were prepared from chick embryos, mouse lungs and rabbit lungs, respectively. Three out of the four vaccines originating from state-controlled institutions in European countries other than Hungary were unsatisfactory; so also were all the three described as "manufactured and marketed in Europe." The age and conditions of storage of most of the vaccines were unknown.

ZIA S. H. & CHANG N. C. Studies of Typhus Fever in Peiping by the Complement Fixation Test. *Proc. Soc. Exper. Biol. & Med.* 1943 Oct., v 69 No. 1 22-3.

Among 20 sera of patients suffering from typhus fever in Peiping only one gave a higher titre reaction with murine than with epidemic antigen in complement fixation tests; five gave equal titres with both antigens; 12 gave titres twice to four times higher with epidemic antigen and one reacted only with epidemic antigen at a titre of 1-640.

The interesting feature of these results is that the authors in previous studies had tended to regard the rickettsiae of human typhus in Peiping as being predominantly of the murine type. They now state that the results of the fixation tests suggest that the rickettsiae both in the autumn and spring, of the past two years were largely of the epidemic type. In their previous studies they had relied on biological tests. [See, for example, this Bulletin 1942, v 39 143, 144 and 615.]

John W. D. Meigs

WESTERN AUSTRALIA. Report of the Commissioner of Public Health for the Year 1947 (Cook C. E. 68 pp., 1 chart. 1948. Perth W. H. Wyatt Govt. Printer).

This report contains two points of special interest to readers of the Bulletin. Firstly, 141 cases of murine typhus were reported during the year: 52 occurred in the Health area of the Perth Municipality; 70 in other Metropolitan areas and 19 from other parts of the State.

It is noted that 7 per cent. occurred in persons under 15 years; 73 per cent. between 15 and 49 and 20 per cent. in those of 50 years or over. The preponderance of cases during working ages suggests that the place of employment, rather than the home is the usual source of infection. The aetiology of the

disease takes on a special importance owing to the frequency of claims being submitted by patients under the Workmen's Compensation Act. It is noted that during the year discussions took place regarding the planning of an epidemiological research into murine typhus in Western Australia, with a view to approaching appropriate bodies for a grant.

During the year, 133 specimens of serum were positive to the Weil-Felix reaction (*Proteus* X19) in a titre of 1/100 or over, as compared with 68, 86 and 100 in the previous three years. Monthly incidence of these results is shown in a table. Broadly speaking, incidence rose from February to April.

The second point relates to leprosy. It is noted that in 2,210 films from 615 patients, there were 555 which showed acid-fast bacilli.

In 1946, 441 smears were positive out of 1,947 and in 1939, all of 5 smears were negative.

H J O'D Burke-Gaffney

RICKARD, E R Complement Fixation in Human Sera following Murine Typhus
Proc Soc Exper Biol & Med 1948, Oct, v 69, No 1, 31-4

The author carried out careful complement-fixation tests on the sera of 404 persons known or suspected of having suffered from murine typhus fever in Florida. In one group of 203 persons the diagnosis was regarded as highly probable and positive reactions occurred in about 86 per cent of the sera. In the other group, of 201 persons, the diagnosis was less probable and the reactions were positive in about 64 per cent. Taking account only of the positive reactions, the average titre in each group was almost the same, 1-21 and 1-22, respectively.

The average titre in a group of 67 persons who had been attacked 12 to 23 months previously was 1-30, in a group of 123 attacked 24 to 35 months previously it was 1-18, and in a group of 94 attacked 36 to 47 months previously it was also 1-18. It appeared, therefore, that there was little tendency to diminution of the titre after two years.

A group of 20 inmates of a New York correctional Institution served as a control, there were only three positive reactions and all these were at a titre of 1-2.

John W D Megaw

HILL, C L & MORLAN, H B Evaluation of County-Wide DDT Dusting Operations in Murine Typhus Control. *Pub Health Rep* Wash 1948, Dec 17, v 63, No 51, 1635-53, 8 figs [10 refs]

The authors describe a large-scale experiment planned for the purpose of finding whether murine typhus could be controlled by dusting rat runs and hiding places with 10 per cent DDT powder.

Three well-defined rural areas in South-West Georgia were selected in two of the areas, with populations of about 20,000 and 10,000 respectively, organized dusting operations were carried out on five occasions between April 1st 1946 and September 30th 1947. The third area was kept as a control. The numbers of cases of murine typhus in the dusted rural areas in each of the years 1945, 1946, and 1947, were 86, 31, and 6, respectively. The corresponding numbers in the control area were 31, 37, and 26. Equally significant reductions were observed in the dusted areas with regard to the percentage of rats showing positive complement-fixation reactions against murine rickettsial antigens, and the degree of infestation of the rats with *Xenopsylla cheopis* and *Leptopsylla segnis*.

There was only a slight degree of reduction in the rate of rat infestation by *Leponyssus bacoti* and *Polyplax spinulosa*.

Full details of the experiment are given in the paper which is likely to become a classic on the subject of the control of infection transmitted from rat to man by fleas.

It appears that the heavy dustings employed caused some deaths among the rats and also gave rise at first to mass exodus of the rats from the dusted localities.

John D. Meyer

LE GAC P. Nouveaux cas de fièvre exanthématique au Togo [Two Further Cases of Typhus Fever in Togo.] *Bull Soc Path Exot* 1942 v 41 Nos. 9/10 604-13 1 chart. [10 refs.]

One of these two cases of typhus-group fever is of special interest in being a striking example of the perplexities that arise in connection with the interpretation of serological findings—these were as follows—

Day of Illness	Weil-Felix titres			Rickettsia-Agglutination titre	
	Pr OX19	Pr OX2	Pr OXA	Epidemic	Murine
18	100	500	50	40	0
22	100	100	200		
27	50	0	50		
31				100	200
35	50	50	50		
43	200	200	100	100	200
52				40	100
				40	0

Complement-fixation tests carried out on an unstated day were positive at a titre of 12-6 with epidemic antigen and negative with murine and tick-bite fever antigens.

Guinea-pig inoculations were carried through 32 passages—the febrile reaction lasted 10-14 days—there was no acrotal reaction—70 per cent. of the animals died and the autopsy findings are said to have resembled those described by some workers as occurring in scrub typhus—no mention is made of the microscopic characters of the exudate.

The author states that the findings are rather disturbing (*prejudicables*) and that they tend to strengthen his formerly expressed opinion that the typhus of the African "savannahs" is nearly related to scrub typhus.

The rash was maculo-papular—a few macules were seen on the hand—there was no eschar.

There is no mention of the epidemiological conditions in which the infection was contracted.

John D. Meyer

BAILEY C. A. DIERCKX, F. H. & PROFFITT J. E. Preparation of a Serological Antigen and a Vaccine for Experimental *Tytrugamshi* Disease (Scrub Typhus). *J Immunology* 1943 Nov. 60 No. 3 431-41 9 figs. 15 refs.]

The authors give full detail of a method by which they have succeeded in preparing potent suspensions of *Rickettsia tytrugamshi*. The process involves repeated differential centrifugation of homogenized yolk-sac cultures diluted in casein hydrolysate solutions.

Three strains of the organism were used and all of them yielded suspensions which showed a high degree of activity in fixing complement and in immunizing

guineapigs Among the six strains of antisera used in the tests antigenic differences similar to those described by other workers were found to exist, but there was evidence of the presence of a common antigen, variable in amount, in all the strains

Further work to detect the degree of protection afforded to vaccinated animals against heterologous strains is being carried out and will be described in a later paper

John W D Megaw

DE MAGALHÃES, O & ROCHA, A Contribuição para o conhecimento do tifo exantemático neotrópico no Brasil [A Contribution to the Knowledge of Neotropical Exanthematic Typhus in Brazil] *Mem Inst Oswaldo Cruz* 1947, Dec, v 45, No 4, 825-45, 12 graphs English summary (7 lines)

In their study of neotropical typhus [tick-borne typhus of the Rocky Mountain spotted fever type] in Brazil the authors were struck by the pronounced tendency of infection to occur in small widely separated patches, and they suspected that this distribution might be due to the presence of infection in animals capable of long-range travel such as goats and deer A goat, a kid and a deer (*Cervus axis*) were found susceptible to intraperitoneal inoculation with the infection so that they were regarded as potential natural reservoirs of the disease

Weil-Felix tests were carried out on these and other infected animals, including a rhesus monkey, two coatis (*Nasua narica*), two wild cats, a rabbit, and a ferret, also in a number of uninoculated kids from various areas in Brazil and on three dogs Nine different strains of proteus were used in the tests—an H and an O strain of *Proteus* X19, *Pr* X2, *Pr* XL and *Pr* XK, and a strain of *Pr vulgaris*

The results of the tests are shown in graphs, from these it appears that the responses were of many different types, and the authors state that they have found the same strain of infection to give rise to a great variety of responses in different animals of the same species

John W D Megaw

TAYLOR, D J, MULRENNAN, J A & THURMAN, D C, Jr Species of Ticks associated with Rocky Mountain Spotted Fever Cases in Florida *J Econom Entom* 1948, Oct, v 41, No 5, 809-11

' On the basis of circumstantial evidence presented, *Dermacentor variabilis* appears to be the most likely vector of spotted fever in Florida The occurrence of *Amblyomma americanum* at the scene of one of these cases is not to be overlooked in view of recent discoveries "

RODRIGUES, P M & TRAVASSOS, J A reação de Bengtson no diagnóstico da febre maculosa das montanhas rochosas [Bengtson's Reaction in the Diagnosis of Rocky Mountain Spotted Fever] *Hospital* Rio de Janeiro 1948, July, v 34, No 1, 55-69, 1 graph English summary [22 refs]

Complement-fixation tests carried out by Bengtson's method were employed in the diagnosis of 10 cases of tick-borne typhus in San Paulo The test was found to be strictly specific in every case and the results obtained with antigens of local origin were identical with those obtained with an antigen supplied from the Rocky Mountain Laboratory, Montana These results furnished additional evidence of the identity of the spotted fevers of the Rocky Mountains and of San Paulo

Five of the cases were fatal, in four of these, sera were examined on the 5th to the 9th day and all were positive, whereas only one was positive with the

Well-Felix test. Sera of six patients giving titres ranging from 1-8 to 1-16 with the homologous antigen were completely negative with antigens prepared from epidemic and murine strains of rickettsiae. *John W. D. Meigs*

FRASER, L. E., ROSENFELT, H. & DANCIGER, J. A. Para-Aminobenzoic Acid in Treatment of Rocky Mountain Spotted Fever. *Amer. J. Dis. Child.* 1948 Apr., v 75 No 4 493-504 1 chart. [Ref. in footnotes.]

Details are given of four cases of Rocky Mountain spotted fever in children who were treated with para-aminobenzoic acid. In three of the cases, treatment was started on the 8th or 9th day and rapid improvement was observed. In the fourth case the first dose was given on the 13th day, but death followed seven days later. This child, aged seven years, received altogether 144 gm. of the drug and an excessive blood level of 282 mgm. was reached at one stage accompanied by extreme acidosis.

The authors do not agree with the observers who claim that the drug, is of low toxicity. They mention in a foot note that some manufacturers are now producing a sodium salt of the drug which does not appear to cause acidosis.

John W. D. Meigs

HARRELL, G. T., MEADS, M. & STEVENS, A. "Aureomycin," a New Orally Effective Antibiotic. Clinical Trial in Rocky Mountain Spotted Fever. Results of Susceptibility Tests and Blood Assays using a Turbidimetric Method. *Southern Med. J.* 1949 Jan., v 42, No. 1 4-12, 4 figs.

In the three cases described, aureomycin appears to have had a strikingly curative action similar to that observed in the larger series of cases reported in the following paper.

The total daily oral dosage was 3.0 to 6.0 gm. given in divided doses every four to six hours.

It is mentioned that the drug rapidly loses its activity when kept in solution, even for a few hours.

John W. D. Meigs

ROSS, S., SCHROENBACH, E. B., BURKE, F. G., BRYAN, M. S., RICE, E. L. & WASHINGTON, J. A. Aureomycin Therapy of Rocky Mountain Spotted Fever. *J. Amer. Med. Ass.* 1948 Dec. 25 v 138, No. 17 1713-18 1 chart. [Refs. in footnotes.]

This paper opens with a brief summary of what is known with regard to aureomycin, a new antibiotic derived from a strain of *Streptomyces aureofaciens* which gives rise to a golden colour in culture media.

The drug was found to protect mice and guinea-pigs against harmful results from inoculation with the rickettsiae of Q fever, rickettsialpox, Rocky Mountain spotted fever and murine typhus. The drug is readily absorbed when given by the mouth and is of low toxicity except when administered intravenously. Doses up to 60 mgm. per kgm. daily for 48 hours cause no toxic effects except occasional nausea and vomiting after the first few doses. References are given to five papers presented at a conference on Aureomycin held under the auspices of the New York Academy of Science on July 1st 1948.

In the present study, 13 patients with Rocky Mountain spotted fever were treated. The ages of the patients ranged from 18 months to 50 years.

The results are described in detail. They are remarkably good, and appear to resemble closely those described by SMADEN *et al.* as occurring in cases of scrub typhus treated by chloromycetin (*this Bulletin* 1949 v 46 27).

The average duration of the fever after the first dose was two-and-one-third days and even in the two patients whose treatment started on the 7th day

of the illness the response was equally satisfactory, whereas in a previous series of cases treated with *para*-aminobenzoic acid no benefit was observed among patients whose treatment started after the 7th day

The dosage adopted was three initial doses of 2-5 mgm per kgm, per os at intervals of one hour, then the same doses every two hours till the temperature had remained normal for two days, then the same doses every four hours. The duration of treatment ranged from four-and-a-half days to nine days, the average total amount of the drug was 9.5 gm, the range being 2.3 to 16.3 gm

In all the cases that came under treatment before the 7th day there was a striking absence of symptoms pointing to the need for supportive treatment

No mention is made of the availability or cost of the drug

John W D Megaw

ORTIZ MARIOTTE, C & CALDERÓN, C Hexaclorociclohexano, su efecto en la garrapata comun del perro en México. Prueba de laboratorio—Informe preliminar [The Effects of Hexachlorocyclohexane on Dog Ticks in Mexico] *Boletín Oficina Sanitaria Panamericana* 1948, Aug, v 27, No 8, 719-23 English summary

The commonest dog tick in Mexico is *Rhipicephalus sanguineus*, which abounds in the northern States, where it is considered to be an important vector of Rocky Mountain spotted fever [this *Bulletin*, 1946, v 43, 1134, 1948, v 45, 165, 252]. The authors describe a number of experiments indicating the lethality of gammexane to ticks. The advantages of this substance and its comparative absence of toxicity to domestic stock suggest that it may enable the control of "spotted fever" to be achieved. Satisfactory results were obtained with DDT in La Laguna in 1947, and the authors suggest that comparative studies be made in areas of Mexico where *R. sanguineus* is prevalent, to ascertain the relative practical and economic values of DDT and gammexane in controlling this vector of the disease

H J O'D Burke-Gaffney

HENI, E & GERMER, W D Q(ueensland)-Fieber in Deutschland [Q(ueensland) Fever in Germany] *Deut med Woch* 1948, Oct 15, v 73, Nos 39/40, 472-6, 5 figs

In September 1947, the author began to observe the occurrence, in villages near Tübingen, of an influenza-like illness in which a considerable number of the patients had symptoms of atypical pneumonia

A detailed study was made of an outbreak of the disease at Remmingsheim, a compact farming community of about 700 persons. The first cases occurred at the end of November, and no less than 260 persons were attacked during the month of December. By the beginning of February 1948, the outbreak came to an end. The total number of cases was 326

The first serological tests were carried out in January, among 21 sera 19 gave positive complement-fixation reactions against Q fever antigen, at titres ranging from 1-32 to 1-1,024. At a later stage 13 other cases were confirmed by complement-fixation tests of patients' sera or of inoculated guinea-pigs. The 32 proved cases belonged to 28 families of whose members 100 were attacked

A detailed clinical description of the disease is given, the only special feature was that altogether seven patients died. Two of the deaths were due to pulmonary embolism, one to a metastatic empyema following gangrene of both feet, the remaining four fatalities occurred in old men who developed hypostatic pneumonia after mild attacks. Radiographic evidence of lung involvement

was found in 23 per cent. of the cases. The severity of the attacks was extremely variable—ambulatory or very mild cases occurred more frequently among women and children than among men.

A brief description is given of outbreaks in three other villages near Tabriz during 1948. In one village of 2 450 inhabitants there were about 300 cases; in another with a population of 4 000 it was estimated that 30 per cent. of the people were attacked.

Most, but not all, of the patients had been associated with cattle. Inhalation of dust derived from dried faeces of infected ticks, the drinking of infected milk, and man-to-man infection by inhalation of infected droplets, are possible modes of transmission. The last-mentioned method would best account for the explosive nature of the outbreaks and the spread of infection through whole families, starting from a single infected person.

Some confusion resulted from the simultaneous occurrence of another short fever in which also atypical pneumonia often occurred: this appears to have been a true virus infection; the catarrhal symptoms were more pronounced, and attacks in infants were much more common than was the case with Q fever. The only reliable method of diagnosis was the complement-fixation test.

John W. D. Meigs

PAYZIN S. Orta anadolu da bir köyde Q humması salgını. [Q Fever Epidemic in Oranek Village.] *Türk İhtisas ve Tıbbi Biyoloji Dergisi* Ankara 1948 v. 8, No. 3 116-23. English summary 124-5.

— Faz Ankara, İzmir çıkışlı Q humması suşları ile bağışıklık deneyleri. [Cross Immunity Experiments with Original Maras, Ankara, İzmir Q Fever Strains.] *Ibid.* 126-9. English summary 130-31.

The epidemic described occurred in a village of Anatolia: there were 20 cases in one of which there was a typhus-like rash.

Rickettsia burnetii was isolated by guinea-pig inoculation: one strain was isolated and identified by R. R. PARKER from a tick (*Ornithodoros lakwani*) which had fed on an infected guinea-pig.

Infection was suspected of having been transmitted by the inhalation of infected dust from wool kept in the hives of the patients. Apart from this outbreak it is stated that many strains of *R. burnetii* have been isolated from patients in many parts of Turkey where the disease is endemic. Guinea-pigs convalescent from experimental attacks were found immune to a Morocco strain, to two Smyrna strains, and to an Ankara strain.

John W. D. Meigs

BROWN D. C., KNIGHT L. A. & JELLINEK W. L. A Fatal Case of Q Fever in Southern California. Reprinted from *California Med.* 1948 Sept. v. 68 No. 3 2 pp.

"The first confirmed fatal case of Q fever in Los Angeles County is reported. The patient's occupation brought him in frequent contact with livestock (is characteristic of about 72 per cent. of the cases so far studied in Southern California). The clinical course was typical of the disease. The patient was the first under 50 years of age known to have died of Q fever. The clinical history and the gross and microscopic pathological findings were consistent with those of a previous fatal case in America. The diagnosis was confirmed by the isolation of *C. burnetii* in experimental animals injected with blood and internal marrow collected at postmortem examination.

JELLISON, W. L., ORMSBEE, R., BECK, M. D., HUEBNER, R. J., PARKER, R. R. & BELL, E. J. *Q Fever Studies in Southern California V Natural Infection in a Dairy Cow* *Pub Health Rep Wash* 1948, Dec 10, v 63 No 50, 1611-18

A detailed examination was carried out on the carcase of a dairy cow slaughtered while excreting rickettsiae of Q fever in her milk, and while positive at a titre of 1-32 with the complement-fixation test against Q-fever antigen. There was evidence that infection had been present for at least two months. The cow was in the fifth month of pregnancy.

Full details are given of the gross and microscopic changes detected in the various tissues, but the authors conclude that none of these changes can with certainty be attributed to infection with Q fever.

The changes include a subacute and chronic focal mastitis and a slight degree of focal cellular infiltration of the kidneys, lungs, and pituitary body.

An extensive series of inoculation tests were carried out on guinea-pigs, suspensions were made of all the important organs of the body, the only ones found definitely infected were eight made from different parts of the udder and one from a supramammary lymph node. One out of four guinea-pigs inoculated with lung suspension became infected, but a further test, in which eight guinea-pigs were inoculated with other lung suspensions, gave negative results. Milk from each of the four quarters of the udder was infected. Blood and other fluids of the cow and the unborn calf gave negative results.

The evidence of infection in the experimental guinea-pigs was the appearance in their sera of complement-fixing antibodies against Q-fever antigens.

John W. D. Megaw

LACKMAN, D. & PARKER, R. R. *The Serological Characterization of North Queensland Tick Typhus* *Pub Health Rep Wash* 1948, Dec 10, v 63, No 50 1624-8

In the present study 30 rabbits were inoculated intraperitoneally with a strain of rickettsia originally isolated from a case of North Queensland tick typhus and maintained since 1945 in guinea-pigs.

Serological tests were carried out on the rabbits at intervals of 14, 16, and 27 days. In each test the sera of 24 rabbits were examined.

No significant agglutination was obtained with suspensions of *Proteus* OX19, Pr OX2, Pr OXK, or Pr XL.

With complement-fixation tests, all the 24 sera gave negative reactions with antigens of Q fever, epidemic typhus and murine typhus. With antigens of Rocky Mountain spotted fever, 22 of the sera were positive, with bouton-neuse fever antigen, 12 were positive, and with North Queensland tick typhus antigen, 13 were positive.

These results were regarded as indicating that North Queensland tick typhus belonged to "the spotted fever group of rickettsiae." The findings are in conflict with those of Plotz *et al* who reported that the reactions against Rocky Mountain and bouton-neuse fever were negative [See this *Bulletin*, 1947, v 44, 204].

Ten of the above rabbits were later challenged with epidemic-typhus infection, and all responded by giving positive Weil-Felix reactions and positive complement-fixation reactions against epidemic typhus antigens. Four other rabbits of the group were challenged with Rocky Mountain spotted fever infection, three of them developed positive Weil-Felix reactions, and all four gave positive fixation reactions against the homologous antigen. Five of the rabbits were challenged with bouton-neuse infection, none gave a positive Weil-Felix reaction, but all gave fixation reactions against bouton-neuse antigen.

The antigenic relationships of the rickettsiae were further studied by carrying out complement-fixation tests on guinea-pigs immunized against various kinds of rickettsiae with the use of antigens prepared from yolk-sac cultures of L. North Queensland tick typhus, by the method described by TORRIS and SHEPARD [this Bulletin = 1948, v. 43, 810]. The table shows the results obtained with "soluble" antigens and rickettsial suspensions; the titres observed when homologous antigens were used are shown for comparison.

Titres / Complement-Fixation Tests of Immune Guinea-Pig Sera. Averages of 20 Tests

Antibers against	Antigen		Homologous Rickettsial Suspension
	Soluble Antigen	Rickettsial Suspension	
N. Q. Tick Typhus	248	128	128
S. African Tick Bite Fever	88	3	64
Boutonneuse Fever	43	10	320
Rocky Mountain Spotted Fever	100	13	40
Rickettsialpox	200	13	160
Maculatum Disease	64	0	328
Murine Typhus	0	0	512
Q Fever (American)	0	0	416

The authors' conclusions are that the disease belongs to the spotted fever group of rickettsial diseases, but that the strain of rickettsia is not "synonymous" with any of the known members of the group.

BARTONELLOSIS

MACCHIARELLI A. Posible nuevo tratamiento para la bartonellosis americana. Auto-hemoterapia intradérmica. Mecanismo bio-patológico de la infección bartonellar. [Possible New Treatment of Bartonellosis. Intradermal Auto-hemotherapy.] *Rev. Ecuatoriana de Hig. y Med. Trop.* Guayaquil 1944 Dec. v. 1 No. 4 341-61 1 folding chart

None of the methods of treatment of bartonellosis hitherto applied, liver extract, vitamins, salvarsan, compounds of arsenic and antimony blood transfusion, etc.—has given very good results. The author has tried what he calls "intradermal auto-haemo-vaccine therapy" and reports excellent results in 8 patients since December 1943—one a boy of 15 years the others adults. In another though the *Bartonella* disappeared from the blood in 6 days, death occurred 4 days later.

The following is the method adopted: 10 cc. of blood are taken into citrate from a vein at the elbow and set aside for 6 hours; then, from the deposit (avoiding the upper layer of leucocytes) is withdrawn by a syringe the amount of blood it is desired to inject—2-3 cc. intradermally and the rest intramuscularly. In a case reported in detail, after 4 weeks of general treatment with vitamins B₁ and C and liver extract, on the 31st day of disease the first injection was given; the second on the 35th, by which time *Bartonella* were fewer; fever still on the 40th when a third injection was given; none were seen when later injections were given on the 46th, 55th, 62nd and 68th days of disease. In one patient the *Bartonella* organisms were not seen after 3 da

in others in 4 days (two cases), 6 and 16 days Vitamin administration consisted of 200-600 mgm of vitamin C (Ascorbicin Squibb) daily intravenously, with 1 cc of Parentosol, but the impression was that these played no specific part in the cure, they merely improved the general condition This treatment seemed to forestall the verrucose, eruptive stage, at all events none of the patients so treated developed verruga

The essential difference between this method and that of autohaemotherapy previously applied consists in the fact of *intradermal injection*, whereas others used the subcutaneous or intramuscular route—on this the author lays great stress
H Harold Scott

YELLOW FEVER

HALAWANI A, ABDEL AZIZ, A & ASHOUR, M A Report presented to H E the Minister of Public Health by the Yellow Fever Mission to Nigeria (West Africa)
J Roy Egyptian Med Ass 1944 Aug, v 27, No 8, 341-90, 4 figs & 2 maps
[29 refs] [Recd 13 Dec, 1948]

PAOLIELLO, A Contrôle da febre amarela e de outras doenças transmitidas por mosquito [Control of Yellow Fever and other Mosquito-borne Diseases]
Bol Oficina Sanitaria Panamericana 1948, Nov, v 27, No 11, 1005-44, 2 maps [89 refs] English summary

This is a summary of some methods of control of the mosquito-borne diseases, yellow fever, malaria, filariasis and dengue. The great part of the article deals with the use of DDT against mosquitoes and of virus as a prophylactic against yellow fever and the use of the viscerotome in diagnosis

DDT is an efficient insecticide, but it has its limitations House-spraying, for example, will not eliminate *Aedes aegypti* whose eggs are viable for a period longer than the spray is effectual It must also be used as a larvicide in domestic water-containers There is need also to search for obscure or hidden foci and destruction of adult insects DDT must be used also in vessels sailing to and from mosquito-infected ports In the prophylaxis of yellow fever, the virus 17D vaccine, long in use, is compared with a neurotropic French strain, it is shown that the former is not easy to preserve and the conclusion is reached that the French strain is better

Viscerotomy specimens of liver obtained from males between 10 and 50 years of age who die in less than 11 days from the onset of a fever will reveal all that is necessary as regards silent areas of jungle yellow fever Studies in Colombia showed that of 352 cases of yellow fever discovered by viscerotomy, 92 per cent were males and 81 per cent were persons between 10 and 50 years of age

Anti *aegypti* measures will be effective against dengue as against yellow fever

In malaria control, DDT is still the basic element, with drug treatment secondary DDT has also done much to solve the problem of filariasis control but a good second is Hetrazan (methyl diethyl-carbamyl piperazine hydrochloride) in attacking the filarial embryos
H Harold Scott

RABIES

REMLINGER & BAILEY. J. Sur les échecs du traitement antirabique. [On the Failure of Anti-Rabies Treatment.] *Bull Acad Nat Med* 1915 v 132, No 3376 398-9

After trauma or emotional disturbance rabies often makes an unexpected appearance in human beings as well as in lower animals some time after a full course of anti-rabies injections has been regularly administered. In explanation of such occurrence the authors advance an interesting hypothesis which in the article under review is considered along the lines summarized below.

When the rabies virus, now regarded as a nucleoprotein reaches a neurone, its action is to interfere with the anabolism of the cytoplasm. Inasmuch as the neurone itself elaborates the substance of the rabies virus which paralyzes it, such interference results in the continued production of new molecules of rabic nucleoprotein, which are conveyed via axis cylinders their prolongations and synapses to healthy neurones, wherein the process is repeated. The effect of this chain reaction is the rapid invasion of all the chief elements of the nervous system, and so rabies occurs.

Such however is not always the sequence of events. Neurones can in certain circumstances as yet imperfectly understood, defend themselves against attack by the virus. The mechanism of defence is that of all living cells against a foreign protein—a precipitation of the latter in an insoluble state *i.e.* flocculation. Under the influence of this defence reaction, therefore the molecules of rabies virus may on reaching the neurones pass from their ordinary colloidal state to a state of flocculation—the first step towards total destruction of the virus which both under natural and experimental conditions, frequently takes place. This phenomenon is termed by LEVADITI "neuro-infections à *infectivité*."

It follows, then that the rabic nucleoprotein once flocculated in the neurones, no longer provokes any cellular reaction the production of fresh virulent molecules is arrested and no disturbance of function ensues.

Flocculation is however a state of equilibrium, essentially unstable and reversible. If then, by any action mechanical, chemical or electrical this equilibrium is upset the state of flocculation passes immediately to one of dispersion, *i.e.* to the colloidal state. Resulting from this change of state the rabic molecules rapidly recover their original properties and, as soon as a sufficient number of neurones has been affected the disease abruptly manifests itself.

In the light of this new hypothesis, the effect of anti-rabies treatment may now be examined. Specific treatment consists in the inoculation of suspensions containing partially virulent or wholly avirulent rabic protein. After a sufficient number of injections, the body fluids acquire tonic properties, evidenced by the fact that the blood serum becomes capable of neutralizing the rabies virus *in vivo*. As soon as ever this stage is reached, the virulent molecules of rabic nucleoprotein, which have invaded the neurones flocculate and such flocculation, in the vast majority of cases is followed by a disappearance of the infective nucleoprotein.

In a minority of cases, however in consequence of undue excitation or inhibition of the neuro-vegetative system (*e.g.* fear anger shock) or in consequence of an upset in the acid base equilibrium of the blood and tissues (*e.g.* fatigue overwork, violent muscular effort) there may occur even after a full course of anti-rabies treatment a reversion on the part of the rabic molecules from

the state of flocculation to the colloidal state—a reversion which accounts for the unexpected onset of the disease and for certain failures of anti-rabies treatment

PLAGUE

HÉRIVAUX, A & TOUMANOFF, C Étude de la "faune pulcicienne domiciliaire" des rats au cours d'une épidémie de peste à Saigon, ses conséquences pratiques [Practical Significance of the Results of Studying the "Domestic Flea Index" in Rats during a Plague Epidemic in Saigon] *Bull Soc Path Exot* 1948, v 41, Nos 5/6, 318-25

From June, 1943, to May, 1944, the authors made regular collections of fleas from the floors of human habitations in Saigon. They considered that from such a flea survey they could obtain information of value in the study of plague transmission.

The fleas they were concerned with were those which had left the rats and were to be found in the dust on the floors of the houses. They record their monthly totals in three tables. One lists the numbers of fleas caught in huts with earth floors, the second those found in stone houses with tiled floors and the third table combines both sets of data. The number of premises is not given.

Of 6,820 fleas collected throughout the year, only 12 were *Pulex irritans*. *Ctenocephalides canis* and *C. felis* were most numerous (6,465) and fleas of the genus *Xenopsylla* (*cheopis* 200 and *astia* 133) less so, but these latter species were more common than *Ctenocephalides* in June and July, during a plague epidemic. *X. cheopis* is the main vector, though *X. astia* is also important, the former being more common than *X. astia* on the floors of the stone houses, while in the huts with beaten earth floors there were more *X. astia* than *X. cheopis*.

Figures are also given to show that numbers of these fleas contained human blood.

As a result of this survey, the authors are convinced that, in Saigon at least, a flea index, calculated from such a survey of fleas caught from among the floor dust of human dwellings, is of more value in assessing the risks of plague transmission than is the usually accepted "*cheopis* index". H S Leeson

FAVAREL, R Le rôle du pou de l'homme dans la transmission de la peste à Madagascar [The Role of the Human Louse in the Transmission of Plague in Madagascar] *Bull Soc Path Exot* 1948, v 41, Nos 9/10, 576-80

The author was unable to find evidence of a significant difference between the virulence of a culture of plague bacilli obtained from the bodies of three lice, the dead body of a child who had died of plague, and of another culture obtained by spleen puncture of the child.

A study of the epidemiological conditions prevailing in Madagascar yielded no evidence to support the view that the human louse had played an appreciable rôle in the transmission of plague from man to man. John W D Megaw,

WAGLE P M & BEDARKAR M K. Pneumonic Plague and its Treatment. *Indian Med Gaz.* 1948 Sept., v 83 No. 9 406-8.

Six cases of pneumonic plague were treated by streptomycin given by the intramuscular route. The usual dosage was 0.66 gm. every four hours till clinical improvement was observed, when the dose was diminished. The total amount given ranged from 15.3 to 38.0 gm.

Five of the six patients recovered. The fatal case was one of secondary pneumonic plague and death occurred on the second day. Two of the patients who recovered had secondary pneumonic plague; the other three had primary attacks. Three of the cured patients received antiplague serum, the usual dose was 40 cc. twice daily. The other two patients who recovered were also given serum and in addition they received sulphamerazine 7.0 to 9.0 gm. in divided doses on the first day then 3.0 to 4.0 gm. daily.

The authors attribute the recovery of the five patients to streptomycin but they advise the use of serum in addition with or without sulphamerazine. It is stated that primary plague pneumonia is often of the lobar type sometimes with "stringy" sputum, sometimes with little or no sputum. Leucopenia is usual in the early stage blood cultures are negative. *John H. D. Meyer*

CHEN T H. A Preliminary Report of Rat-Poison with Red Squill, "1090" and ANTU. *Chinese Med J Shanghai*. 1948 July v 63 No. 7 384-6.

1. Red squill, when used in a concentration of 10 per cent. as bait containing animal fat gave results comparing favorably with those obtained with barium carbonate.

2. 1090 proved, as in the United States so also in China, a most efficient rat poison, but it must be handled and used by specially trained workers only.

3. ANTU was found in Foochow to be almost as effective against *R. rattus* as against *R. norvegicus*. Prospects for utilizing it for universal rat poisoning campaigns in China are therefore good and since ANTU acts in contact its application could be rendered fairly safe.

CHOLERA

OMAR, W & VASSILIADIS P C. Study of the Vibrios Isolated at El-Yor Quarantine Camp during the Pilgrimages of 1941-42 and 1942-43. *J Roy Egyptian Med Ass* 1943, Oct. v 26 No 10 348-54.
[Recd. 13 Dec. 1943.]

1. During the pilgrimage of 1941-42, vibrios were found in "28 per cent of the stools examined, while in only 0.56 per cent were they found in the 1942-43 pilgrimage. As during this last pilgrimage, there were no Indian pilgrims at the Hedjaz, this might probably explain the smaller percentage of vibrios found in this year.

2. Agglutinins were found, in the sera of carriers of non-agglutinable vibrios against some of these vibrios especially against one particular vibrio (*A. N. 27*) which was agglutinated by its carrier serum in 1/800. It is assumed that these agglutinins represent normal antibodies.

3. Some characters of the non-agglutinable vibrios isolated from the 1941-42 and 1942-43 pilgrimages are described. It is of interest to note that while in both groups the majority of these vibrios belonged to fermentation

group I of Heiberg, all the other vibrios of the first year belonged to group V, whilst all the rest of the second pilgrimage belonged to group III except one that belonged to group II "

FELSENFELD, O Antigenic Relationship of *Salmonellae* to Inaba Strains of *Vibrio comma* isolated in Egypt *Proc Soc Exper Biol & Med* 1948, Oct, v 69, No 1, 95-6

GOHAR and MAKKAWI found that strains of the cholera vibrio from the recent outbreak in Egypt were agglutinated by *Salmi enteritidis* sera [this *Bulletin*, 1948, v 45, 706] The present author tested 3 strains of the vibrio (Inaba type) obtained from the Egyptian epidemic against 25 O, 2 V₁ and 39H *Salmonella* sera Live antigens were used and the preparation of antisera and the technique of agglutination and absorption tests were carried out according to standard methods, which are quoted

The results are shown in detail in three tables, which show that agglutination occurred with dilutions of various *Salmonella* sera as high as 5 to 25 per cent of their titre against the homologous *Salmonella* when the serum contained agglutinins for the *Salmonella* antigenic factors I, XII or g Absorption tests confirmed that parts of these three antigens were present in the strains of cholera vibrio Sera prepared against the latter also agglutinated *Salmonella* strains containing the three antigenic factors quoted The author therefore shows that the three Inaba strains ("K", "4" and "8") of the cholera vibrio isolated recently in Egypt harboured fractions of *Salmonella* I XII and g antigens
H J O'D Burke-Gaffney

TAO, S C, WOO, M O & LOH, W P Clinical Observations on 687 Cases of Cholera *Chinese Med J Shanghai* 1948, July, v 66, No 7, 377-84

The findings in 687 cases of cholera in Shanghai, in which the diagnosis was confirmed by the isolation of the vibrio, are examined and tabulated The majority of the patients were poorly educated labourers and vagabonds and their families Incidence was at all ages from 3 to 77 years and highest in the 21-30 age group There was a preponderance in males over females of 5.3 The disease occurred in 83 per cent of those whose inoculation history could be ascertained

The figures given for the percentage of cases showing different symptoms are in accordance with usual experience Uraemia was the most serious complication and occurred in 27 patients (3.9 per cent) of whom 8 died, giving a mortality rate of about 30 per cent

In discussing uraemia, developing after the acute stage with retention of non-protein nitrogen, it is considered that haemorrhages in the cortex and damage to the tubules result from the effect of prolonged or severe circulatory disturbance, restoration of efficient renal function being delayed or failing to occur even after dehydration and collapse have been corrected It was noted that many uraemic patients "developed generalised oedema of mild to moderate degree when slight excess of saline was pushed parenterally in an attempt to promote urinary excretion"

In uncomplicated cases the average duration of illness was 4 to 5 days and with uraemia 7 to 8 days Treatment was by intravenous transfusion of normal saline and with 0.5 per cent sodium bicarbonate in half-normal saline Glucose-saline was given in cases of relatively prolonged course or when there was uraemia and acidosis At a period when the saline solution used was known not to be pyrogen-free the majority of patients had febrile reactions after transfusion When pyrogen-free saline was used, mild or moderate fever occurred in only 31.5 per cent of cases

The case mortality rates experienced in India and China at periods when different methods of treatment were used are shown in a table for comparison. From a figure of 89 per cent (in Calcutta in 1895-1905) there has been a striking drop in the death rate following the introducing of treatment by saline transfusion and experience of the use of the method. In the present series of bacteriologically confirmed cases in Shanghai the rate was 4.7 per cent, and including cases diagnosed clinically the figure was 6.2 per cent. The highest mortality rate was in the age group 0-10 years (17.9 per cent.)

No statistical interpretation can be placed on the results of a short series of 41 cases treated with 1 gramme of sulphadiazine orally every 4 hours for 4 or 5 days along with an equal amount of sodium bicarbonate. A general impression was gained that the treatment reduced the severity and duration of the attack. The authors are highly sceptical of the likelihood of any striking effect being obtained by chemotherapeutic treatment in cholera in view of the nature of the disease in which the primary requirement is the replacement of fluid.

In a daily bacteriological examination of the stools of 218 cases, until two successive negative cultures were obtained, it was found that 80 per cent. were negative on or before the 6th day; none of the cases was positive beyond the 8th day.

J. Telle

SINGER, E., WEI S. H. & HOA, S. H. Cholera Immunisation. *J. Immunology* 1948, Oct., v. 60 No. 2, 181-7

The response to immunisation with cholera vaccine prepared in different ways was tested in human subjects. An Ogawa strain isolated in Nanking was used for the preparation of the vaccine, no penicillin of the growth on beef extract agar being first prepared by washing off with physiological saline solution. The suspensions were treated in the following ways:—

1. Heating at 55° to 56°C. for 30 minutes and preserving with 0.5 per cent. phenol.

2. Adding 0.3 per cent. formalin to kill the vibrios and preserving with 0.5 per cent. phenol.

3. Immersing the containers in boiling water and maintaining the temperature at 100°C. for 30 minutes, 0.5 per cent. phenol being subsequently added.

4. Adding absolute alcohol to a concentration of 75 per cent. and then diluting to the required vibrio content (8,000 million per ml.) with alcohol adjusted to 20 per cent.

[Vaccine of the type very commonly used, in which the only treatment employed is the addition of phenol, was not tested.]

The experimental subjects were given subcutaneous injections of 4,000 million, 4,000 million and 8,000 million organisms at intervals of 7 days. The reactions to inoculation were insignificant and did not vary appreciably with any of the types of vaccine used.

In a first series of subjects no significant difference was found in the agglutination titres of those given either the vaccine heated at 56°C. or the vaccine treated with formalin or alcohol. Vaccine heated at 100°C. appeared to give a better antibody response but in a second series in which the vaccines heated at 56°C. and 100°C. were compared this difference did not occur. A chance variation or some extraneous factor had been responsible for the first finding.

The effect of intracutaneous 100°C. was also tested. 0.1 ml. followed by 0.1 ml. significantly from that of

subcutaneous
injection
antibody

heated at 56°C. and
subcutaneous injections
that did not differ
route with

the larger doses. When three intracutaneous doses of 0.2 ml were employed the agglutination response obtained was higher than by any other method. In some instances, however, a small abscess formed about 4 to 6 days after the third injection. "Although these abscesses were quite insignificant and their formation was not accompanied by any marked discomfort they must be considered as an undesirable complication and, at present, a contraindication against the use of intracutaneous vaccination in cholera prophylaxis."

In a previous communication [this *Bulletin*, 1949, v 46, 37] the authors had described the effect of filtrates of cultures of *V. cholerae* in causing shedding of the epithelium of the ileum of the guinea pig and the neutralization of that effect by rabbit serum containing antibodies against the somatic antigen of the vibrio. The same effect was obtained with the sera of immunized human subjects during the course of this study. The neutralizing antibodies were removed by absorption with a boiled suspension of *V. cholerae*.

The antibodies produced by the vaccines prepared in different ways were shown to be identical by cross absorption tests. J Taylor

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

DE FIGUEIREDA, J. M. P. A carência alimentar e a parasitose intestinal (anquilostomíase e amebíase) no determinismo da úlcera duodenal (Contribuição para o estudo de patologia regional) [Avitaminosis and Intestinal Parasitism in the Aetiology of Duodenal Ulcer] *Bol. Geral de Ucd Nova Goa* 1947, Jan-Dec, Ser 29, Nos 1/12, 27-42.

The author puts forward the view, and gives notes of nine cases in support of his thesis, that food deficiencies associated with amoebiasis or ankylostomiasis have some aetiological connexion or play a part in the causation of duodenitis and duodenal ulcer. The author bases his statements on experience of several years' observation [but it is not clear, and it would be difficult to demonstrate, that the conditions are aetiological connected and not merely chance concomitants]. H Harold Scott

RICKARDS, A. G. On the Incidence of Protozoal and Bacillary Intestinal Infections in Men of the Royal Air Force returning from Service in Tropical and Subtropical Lands. *J. Trop. Med. & Hyg.* 1949, Jan, v 52, No 1, 2-11 [38 refs].

The purpose of this paper is to record the results of certain investigations undertaken in the examination of R.A.F. officers and men immediately prior to their demobilization. All were examined immediately after disembarkation from overseas. The subject is discussed under three main headings, namely: the post-clinical histories of diarrhoea and dysentery, the incidence of various protozoal organisms and their relationship to previous clinical history in a similar group, and the pathogenesis of *Entamoeba histolytica*. In the delineation of the geographical area two broad distinctions were made, namely Indian and Mediterranean theatres. The questionnaires from 22,200 men were examined, representing an unselected sample. For simplicity's sake, all cases of dysentery or severe diarrhoea that were not protozoal, were classified under the heading of "bacillary dysentery". The principal value of the figures obtained is to be found in their comparison rather than in their absolute totals. All faeces examinations were carried out by the author so accordingly the personal error has been kept more or less constant. In 2,000 cases, some 2,500

specimens were examined and all in which *E. histolytica* was suspected or diagnosed on the initial preparation were re-examined in a freshly-ripened specimen. It was possible to examine one specimen only and therefore an adjustment has to be made so that the true incidence is about three to five times that established by a single examination (see this *Bulletin* 1933, v 22, 220). Calculation in this fashion would give the true incidence of *E. histolytica* as follows:—

Mediterranean group 16.41 to 17.35 per cent.

India group 91.89 to 96.65 per cent.

and the incidence of non-pathogenic protozoa as

	India group	Mediterranean group
<i>Eutamias col</i>	15.1	18.1
<i>Endolimax nana</i>	10.00	7.5
<i>Iodamoeba bitumella</i>	3.8	3.05
<i>Giardia lamblia</i>	0	2.13

The incidence of amoebic dysentery was nearly seven times as high among those returning from the Indian area (1.78 per cent. against 0.28 per cent). On the results obtained from this survey it can be estimated that about half a million men might be expected to return from overseas harbouring *E. histolytica*. The incidence of *E. histolytica* has not been found to vary between two groups of men composed of those who had suffered from bacillary dysentery and those who had not. The variation in the incidence of the parasite is not significant between those giving a past history of dysentery and those who had been free from it but that of *E. histolytica* is significantly higher in those presenting a past history of amoebic dysentery. It is suggested that the strain of *E. histolytica* which affected men in the Indian theatre is of greater virulence than that endemic in the Mediterranean.

The clinical histories of 25 symptomless cyst-passers were followed up for periods of 6–10 months and showed that three of the men developed symptoms of gastro-intestinal dysfunction probably related to the parasitic infection.

P. MASON-RAB

BERTRAND-FONTAINE Mme FAUVERT R. & SCHWETZER J. Trois observations d'abcès sigues ambulants du foie [Three Cases of Amoebic Abscess of the Liver seen in Paris.] *Bull. et Mém. Soc. Méd. Hôp. de Paris*, 1948, Vol. 30/31 1079–83 1 fig.

During the past year the authors in Paris, have discovered three cases of abscess of the liver in patients who have never been out of the metropolis.

In one active forms of *E. histolytica* were demonstrated in the liver pus and cysts were found in the faeces.

P. J. de la BARRA

BLAS RUIZ, H. GRUNY E. & SCHOUTEN G. Primer caso de absceso hepático por entameba disenterica, observado en el Paraguay. [First Case of Amoebic Abscess of the Liver recorded in Paraguay.] *A. Facultad de Ciencias Med. Asuncion Paraguay* 1948 June 1, R. No. 23 247–55 5 figs.

The following is a translation of the authors' summary:—

The authors describe the first case of liver abscess caused by dysenteric amoebae in Paraguay. The patient was a Netherlands priest who had probably contracted the disease in Turkistan 20 years previously. Operation in Paraguay

in February 1942, together with previous radiological examination, revealed the presence of a right hepatic abscess which had extended into the thorax. Microscopic examination showed entamoebae resembling those described by Councilman and Lafleur. Treatment consisted of emetine injections and tablets of yatrien and stovarsol. The patient was discharged cured within three months.

EL KORDY, M I On the Cultivation of *Entamoeba histolytica* in Hydatid Fluid. *J Roy Egyptian Med Ass* 1944, Aug, v 27, No 8, 329-40 [20 refs] [Recd 13 Dec, 1948]

ERDEI, A Pulmonary Tuberculosis complicated by Amoebic Hepatitis [Memoranda] *Brit Med J* 1949, Jan 1, 18

A woman of 36, who had had pulmonary tuberculosis for some 10 years, had been complaining for 8 of those years of dragging pains in the right iliac fossa, and more recently, in the right epigastric region. The pains were independent of food, worse on standing and were increasing in frequency. The bowels were regular and the stools macroscopically normal. The patient had had three or four attacks of diarrhoea, lasting a few days each, between 1939 and 1944, it appears that blood and mucus were passed on two occasions. The patient had never been in tropical countries, but had been on trips to Paris, the south of France and the Dalmatian coast before the war.

The caecum proved to be ballooned, doughy and tender. A small area of tenderness was detected in the right lobe of the liver, about 2.5 cm to the right of the xiphoid process, and was most pronounced in the intercostal space above. On screening, the right diaphragm was slightly elevated, with diminished movement. On sigmoidoscopy, the rectal mucosa proved to be congested and oedematous, with several submucous haemorrhages and a few small healed ulcers at 10 cm.

There was some hypochromic anaemia, leucocytes were 3,600 per cmm with normal distribution. Among the laboratory tests it is noted that the nicotinic acid tolerance was 450 mgm. Examination of the stools revealed two typical cysts of *Entamoeba histolytica* in the sixth specimen.

The patient was treated with 10 injections of emetine, together with penicillin, and diodoquin and consecutive emetine bismuth iodide and carbarson were given. The liver became very tender after the second emetine injection, but the tenderness disappeared after the sixth.

More attacks of diarrhoea occurred after the improvement from the specific treatment. Later examination revealed the presence of *Giardia intestinalis* in the stools and of *Shigella flexneri* in a sigmoidoscopy swab (but not in the stools). The patient recovered after treatment by sulphasuxidine and *Ec* motions do not now exceed two daily.

The author points out that abdominal tuberculosis figured too prominently in the differential diagnosis and stresses the need for keeping chronic amoebiasis in mind when dealing with obscure conditions. He also points to the value of a rapid liver-function test, such as that of nicotinic acid tolerance.

H J O'D Burke-Gaffney

VERNER, H D Pulmonary Amebiasis due to Hematogenous Spread: Report of a Case. *Bull Charlotte Memorial Hosp* Charlotte, N Car 1948, Dec, v 3, No 1, 3-6

This paper records the rather curious story of a 55-year-old man whose symptoms were directed to his general condition rather than to the tract. These consisted of generalized abdominal pain, a prodromal stage, been common, true, me

liver. There were occasional attacks of diarrhoea with occasional tarry black stools. During this time he was treated, at intervals, with emetine without obvious improvement. On admission to hospital attention was directed to the physical signs at the base of the left lung where on X-ray examination, a non-homogeneous ill-defined consolidation was revealed, while subsequent instillation of Epi-dol showed the appearance of bronchiectasis. Consequently a left lower lobectomy was performed. No specific diagnosis was made but bronchiectasis was not confirmed. Further X-ray films showed consistently a small amount of fluid at the left costo-phrenic angle. One month later a posterior thoracotomy was done and the purulent fluid was drained. The patient was discharged apparently well. Two weeks later he became acutely ill with cough and respiratory signs necessitating a repeated thoracotomy. Subsequently a raised fluctuating swelling appeared in the right upper abdominal quadrant which, on incision, yielded a large amount of thick, creamy pus. From this time onwards he gradually developed septicaemia and eventually died.

At autopsy a typical amoebic ulcerative colitis was revealed extending from the caecum to the descending colon and in the liver there were two large abscesses in the right lobe together with thrombophlebitis of a large radicle of the hepatic vein. This radicle emanated from one of the abscesses and contained a firm adherent thrombus which extended into the vena cava at the junction with the hepatic vein. Histologic sections revealed the presence of numerous *E. histolytica* in the margins of the intestinal ulcers and in the wall of the liver abscesses. renewed search of the sections of the lung, obtained by previous lobectomy also revealed numerous amoebae in the lung tissue.

Two factors were responsible for failure to recognize the true condition in the first instance. In the first place repeatedly negative laboratory examinations of sputum and faeces tended to discourage the diagnosis of amoebiasis and in the second it was difficult to reconcile the position of the lung abscess on the assumption of amoebiasis.

It is claimed that this case illustrates the mechanism of septicaemia. If the organisms travel through the portal system, producing a liver abscess, the latter may give rise to a thrombophlebitis of the hepatic vein, thus creating a secondary focus of dissemination. It is assumed that the liver abscess which was not clinically evident, antedated the pulmonary abscess.

DE SALVE A. Sopra un caso di amebiasi e sintomatologia setticemica. [A Case of Amebiasis with Septicaemic Manifestations.] *Bol Sanitario d. Tripoli* Jan.-June v 6 Nos. 1/2, 4-7

The English summary appended to the paper is as follows —

"The author describes a case of amoebiasis which because of its symptomatology is defined as a case of amoebiasis with unusual septic characteristics.

"After having discussed the case from the clinical point of view he gives the pathogenic interpretation of it by postulating that *Entamoeba histolytica* can produce besides the known cytolytic, also a substance capable of toxic action and responsible for the peculiar symptomatology shown by the patient."

the history

ducts, thus suggesting the clinical hypothesis of cholecystitis. The patients showed steady or intermittent pain in the hepatic region, tenderness over the vesicular area, nausea before breakfast, and certain dyspeptic-pain symptoms caused by foods, especially fatty foods. Cholecystography and duodenal intubation did not reveal any abnormality in these patients, feces examination was positive for *Endamoeba histolytica* and the apparently vesicular symptoms disappeared with the specific antiamebic treatment. Such cases are explained by the author to be due to general toxic manifestations acting sporadically upon the vesicular functions, and perhaps, in some cases to a colitis predominating on the hepatic flexure.

"In view of the relative frequency of intestinal amoebiasis the author calls attention to the fact that this organic colonopathy should be mentioned, at the side of the functional, in differential diagnosis of chronic cholecystitis."

CLERC, S & BERGERET, C. Quelques observations d'aspects chirurgicaux de l'amibiase intestinale [Some Notes on the Surgical Aspects of Intestinal Amoebiasis] *Bull Méd de l'Afrique Occidentale Française* 1947, v 4, No 4, 415-20

This short paper consists of brief clinical notes on the cases of eight patients. In three cases abscesses in the right iliac fossa were incised and amoeba were subsequently found in the pus in two of them, in one patient, who was found at necropsy to have multiple liver abscess with amoebae in the pus, perforation of the caecum led to fatal peritonitis, in one patient the diagnosis was made during operation for supposed appendicitis, by the appearance of the caecum which was oedematous and covered by a veil of loose adhesions, whilst the appendix appeared to be normal. The remaining three patients had masses in the left iliac fossa due to perisigmoiditis, two of these suppurated and needed incision, but no amoebae were found in the pus, whilst the third resolved under emetine treatment. All three patients had symptoms of subacute intestinal obstruction and radiological examination after barium enema showed this to be due to pressure on the colon. Emetine treatment brought about rapid improvement and confirmed the diagnosis. The demonstration of amoebae in the granulations forming after incision of an abscess in two cases is so rare that the authors have included a short abstract of a paper on this subject by TOURAINE and DUPERPAT, in which cutaneous amoebiasis is divided clinically into (1) infection by extension (a) following incision of an abscess, (b) perianal, (2) by inoculation (a) cutaneous, (b) genital, (3) allergic dermatoses in patients suffering from amoebic dysentery. Amoebae are found in the stools in 35 per cent of these patients.

LAVIER, G, CROSNIER, R & MERLE, F. Le traitement de l'amibiase par la conessine [The Treatment of Amoebiasis with Conessine] *Bull Soc Path Exot* 1948, v 41, Nos 7/8, 548-53

A preliminary report [this *Bulletin*, 1948, v 45, 1086] has already appeared from this source on the use of extracts of *Holarrihena africana* [*floribunda*] in the treatment of amoebiasis. This followed the demonstration by DURIEUX *et al* [*ibid*, 905] of the therapeutic activity of conessine in amoebiasis.

Forty-two cases of acute amoebiasis constitute the material for the present report, of which 40 were repatriates to France from the Far East, and 2 from North Africa. With the exception of 3, all these patients had previously been treated with emetine on 3 to 6 occasions. Emetine resistance is common among those repatriated from the Far East; it is either a partial or complete "true resistance to the drug, or a "pseudo resistance" which is amenable to treatment

Both the hydrochloride (13 cases) and the hydrobromide (8 cases) or salt of conesine were used. The drugs were given orally. Initially the dose was 0.5 gm. daily; this was reduced to 0.4 gm. or 0.3 gm. daily if intolerance was manifested. The gross dosages ranged from 3.5 gm. to 6.8 gm. a daily 3.0 gm. were given over a period of two weeks. There was no evidence of "true" toxicity of the compounds; the side-effects chiefly encountered were tremors of a Parkinsonian type (13 cases) and insomnia, nightmares and disturbances of sleep (20 cases). There was improvement in the general health in all cases under treatment and the stools rapidly were restored to normal. Rectoscopic examinations showed the mucosa to have healed completely (13 cases) or substantially (12 cases) after the conesine course.

Seven of 10 cases on re-examination 6 weeks after the conclusion of treatment had no parasites in the stools (number examined unspecified). Of the other three patients one was passing loose stools containing amoebae; the remaining two were passing cysts. All these three were again rapidly sterilized by retreatment with conesine. As conesine is not invariably successful in eradicating an *E. histolytica* infection, it should be followed by further therapy to forestall relapse; suggestions are made as to the nature of this after-treatment.

[The words cure and sterilization are used in this paper for clinical cure and "temporary absence of parasites from the stools" respectively. The claims that the results of conesine treatment are brilliant and that the drug is superior to emetine in the treatment of amoebiasis do not appear to the reviewer to be substantiated by the evidence presented.]

CHOU T. C. & JANG C. S. Chemotherapeutic Studies on Ya Tan Tze. 2. Ya Tan Tze (*Brucos javanica*) on Experimental Amebiasis. *Chinese Med J Shanghai*. 1948, July v 63, No. 7 330-63. (14 refs.)

"Ya Tan Tze the seed of *Brucos javanica*, and its crystalline principles, substances A, B and C have been tested for their therapeutic value on experimental amebiasis in dogs. The whole kernel of the drug is highly effective in eliminating the parasite but the survival periods of the treated animal are not prolonged. The substance B a phenolic compound, acts like the crude drug and may therefore represent its active principle. In the doses used both the crude drug and the substance B produce vomiting and diarrhea and other signs of gastro-intestinal irritation. The other two principles A (an organic acid) and C (a glycoside) have been tried on one case each and the result are therefore inconclusive."

SORRY H. J. A Note on the Treatment of Amoebic Infection with *Brucos javanica* Seeds. *Chinese Med J Shanghai*. 1948, July v 63, No. 7 363-5.

A cold aqueous extract of *Brucos javanica* seeds was found to be highly amoebicidal *in vitro*; hot aqueous extracts were feebly so and alcoholic extracts were not amoebicidal [for earlier work on this plant see this Bulletin, 1937 v 34 855].

Twenty-eight Chefoo University Hospital employees found to be passing *E. histolytica* cysts were treated orally thrice daily for ten days with 0.1 gramme pulverized decorticated seeds of *B. javanica*. Nearly half of these persons suffered from nausea and vomiting while on the drug, one so severely that the treatment had to be stopped; a few had dizziness or mild diarrhea; no individuals suffered no side effects at all. Two months later the stool of 35 of these patients were re-examined and 17 of them found still to be passing cysts.

Seventeen patients with acute amoebic dysentery were similarly treated by the oral route, either *ab initio* or after a few preliminary injections of emetine. Improvement followed in every case, and 2 patients appeared to be sterilized of their infections four weeks after conclusion of treatment, while 10 showed no *E histolytica* at the end of treatment. DFSCIENS R, LAMY, L & MARCHAL, G Mlle Sur un flagelle indetermine isolé des selles d'un français revenant de Guinée [An Unidentified Flagellate isolated from the Stools of a Frenchman returned from Guinea] Bull Soc Path Exot 1947, v 40, Nos 11/12, 435-9, 4 figs

In the stools of a Frenchman returned from Guinea, the authors found *Dientamoeba fragilis*, *Eutamoeba histolytica* and a flagellate at first identified as *Trichomonas hominis*. They isolated and maintained cultures of an amoeba and the flagellate, however, at the end of a month they lost the amoeba, but the flagellate culture was maintained for over three months, by means of numerous subcultures. The medium they used was coagulated horse serum, Ringers' solution, rice starch and "1 162F" [no indication of the composition of this is given] in a concentration of 1 in 1,000, with periodic transfers to whole egg with the same medium (containing 1 162F) added.

It was soon realized that the flagellate was not a *Trichomonas*. It was round, 7µ in diameter, with three flagella and no undulating membrane, it had a large nucleus with a large central karyosome, in a single mass at the periphery of the cytoplasm. The characteristic feature was a large club-shaped appendage, 4µ in length that protruded from the body of the flagellate. *Joenia annectens*, in Grassi and other authors have described a flagellate, *Joenia annectens*, in termites with a similar pseudopodic protusion but this parasite differs from *Joenia* in other respects. The authors consider that it has the characters of an *Enteromonas*, but of a species not previously described. They have named it *Enteromonas hercynica* n sp, pending further study to decide if it constitutes a new genus. L E Napier

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

VIGORS CARL G K La fiebre recurrente [Relapsing Fever] Rev Ecuatoriana de Hig y Med Trop Guayaquil 1944, Dec, v 1, No 4, 362-72, 1 fig, 1 chart & 1 map [24 refs]

The English summary appended to the paper is as follows —

- 1 Three cases of relapsing fever diagnosed by the discovery of *B recurrentis* in the blood examination, are described
- 2 All of the cases acquired their infection in the Province of Esmeraldas where infection is most likely to occur are indicated
- 3 The localities within the province and adjacent Colombian territory in *Enteromonas*, but of a species not previously described. They have named it *Enteromonas hercynica* n sp, pending further study to decide if it constitutes a new genus.
- 4 An account of the occurrence of the disease in adjacent Colombian territory is given
- 5 The heightened susceptibility of Europeans, white Americans and non-resident Ecuadoreans to the disease is pointed out
- 6 The probable role of *Orrhodossia venezuelensis* described by Leon, as a transmitting agent from animal to man, is commented upon
- 7 Animal reservoirs (mammals) are listed
- 8 Some aspects of treatment with arsenicals and penicillin are considered

LEPROSY

HAMERS, S. L. T. M. & HERMANS, E. H. Enkele waarnemingen bij leprospatiënten in Nederland. [Some Observations on Leprosy Patients in the Netherlands.] *Aardrijksch. v. Geneesk.* 1948, Oct. 23 v. 9 (n) No. 43 3409-19 6 figs. on 3 pls. English summary

In a rather discursive paper some data are given upon 40 new leprosy patients segregated in the leprosy centre in Holland. There appears to be no evidence that the infection was contracted in the former Japanese prison camps in the Dutch East Indies. The earliest symptoms were occasionally directed to the nose more commonly to fatiguability but most frequently there was an eruption symptoms of nervous irritability or nerve injury. The Mitsuda reaction gave accurate information upon prognosis, whilst the new American classification compared favourably with its forerunner. It can be correlated to the bacteriological and patho-anatomical findings. P. Manson-Bahr

[New Chromogenic Cultures of Acid Fast Bacilli Isolated from *Culex* Mosquitoes fed on Leprosy Patients.] *Mém. Inst. Oswaldo Cruz.* 1947 Dec., v. 45 No. 4 793-812 4 figs.

The English summary appended to the paper is as follows -

"The author describes three new samples of cultures of acid-fast bacilli isolated from wild mosquitoes experimentally fed on active cases of leprosy in the South of the State of Minas Gerais, about 1 mile distant from Santa Fé Leprosy Colony

All those cultures are chromogenic and germinate quite well on Loewenstein medium and in glycerinated broth (forming thin veils) on the surface of this medium without clouding it.

Out of 100 slides smeared with intestinal contents from wild mosquitoes fed on leprosy, 22 were positive for acid-fast bacilli similar to those of Hansen and out of 100 slides smeared with domestic mosquitoes captured in leprosy dormitories, 90 were also positive

"Fifty smears from mosquitoes captured on horses were negative for typical acid-fast bacilli.

RABELO, F E A Aspectos do diagnostico diferencial da lepra [Points in the
 Differential Diagnosis of Leprosy] *Bol Serviço Nac de Lepra* Rio de
 Janeiro 1945, Mar, v 4, No 1, 40-51

This article is one of a series of notes for a course of lectures on leprosy for
 members of the National Health Service, apparently delivered, at all events
 prepared for, in 1942 This one deserves special mention because it brings
 together and points out in tabular form the differential diagnosis between
 leprosy and skin conditions which in one or more aspects resemble leprosy
 Lack of space precludes their being recorded in detail here, but the general
 lines of treatment of the subject should be indicated The diseases mentioned
 are syphilitic roseola and leuco-melanoderma, polymorphic exudative erythema,
 erythema nodosum, centrifugal annular erythema, psoriasis, vitiligo and pinta
 In each case, the site commonly involved is stated and the appearance, the
 course and the histology of the lesions This information can be found in
 publications dealing with leprosy and the better works on cutaneous diseases,
 but it is very convenient to have them collected thus in a single contribution
 by a leprologist of repute

known concerning the occurrence of visceral
leprosy. The author has had under his care
of age who had at the age of 7½ noticed a
his right thigh with definite contour red in
1.5 to 8 cm. in diameter when a similar spot
right arm, with alteration in sensibility and
pt. When the author saw him the macule
and there was diminished sensibility to heat

Smear were seen in smears of the cutaneous lymph. Biopsy
specimens were taken of the skin, the liver, a mesenteric gland, epiploon and
the sternal marrow under a general anesthetic. In the gland and epiploon
Myco leprae were seen and in smears of the liver [but, later, under the de-
scription of the separate tissues is the statement that "bacteria were not met
with on direct examination"] In the tissues lymphocytic infiltration was
observed, with eosinophil increase and histioid proliferation which the author
interprets as indicating that tuberculoid leprosy is not confined to the skin and
superficial glands but is a generalized condition affecting all the organs, setting
up pathological processes different from those of the lepromatous form

RAJAH Z. J., RAJ M. P. & COCHRANE, R. G. A Short Note on Experimental
Investigations on the Optimum Dose of Hydnoctarpus Preparations at the
Lady Willingdon Leprosy Sanatorium, Chingleput, S. India. *Leprosy in
India* 1948 July, v 20 No. 3 146-8

Tests have been made to find the optimum dose of hydnoctarpus preparations
by the use of 10 cc. 10-15 cc. and 15-25 cc. respectively in different groups of
cases with the result that 15 per cent. became negative on the highest dose
against only 9 per cent. on the lowest one but as the lower-dose group included
more advanced cases the test was repeated, with a better distribution of cases.
This showed 18 per cent. became negative on the high 33 per cent. on the
medium and 24 per cent. on the lowest dose. Further tests were carried out
with intradermal injection only, subcutaneous injection alone or both methods
combined and the combination of methods gave the best results which were
confirmed by a repetition of the test.

BICHELLI L. M. & ROIZBERG, A. Terapêutica chaulmoogrica da lepra. A
eficiência do chaulmoogra, de acordo com o estudo de 2.201 casos de alta.
[Chaulmoogra in Leprosy. A Study of 2,201 Patients.] *Arquivos do Serviço
Vac de Lepra*. Rio de Janeiro. 1948, Dec., v 4 No. 7 303-74 1 graph.

This contribution analyzes the 2,201 cases, some of which were referred to
in the preceding abstract. Of 411 of the lepromatous type 224 had prevented
themselves with relapse, 163 remained out and apparently well 1 had died,
8 had been transferred elsewhere and 2 had ceased to attend for treatment.
Of 1,221 "non-characteristic" 229 had relapsed, 808 were at liberty 60 had
died, 31 had gone elsewhere and 2 had ceased to attend of 549 of the tuberculoid
form 57 had had relapses 471 were up and about 24 had died, 16 had been
transferred and one discontinued treatment.

H Harold Scott

ROTBERG, A & BECHELLI, L M Terapêutica chaulmoôgrica da lepra Resultado do tratamento chaulmoôgrico na lepra observações pessoais e estudo de 2,201 casos de alta registrados em nosso serviço [Personal Observations on 2,201 Leprosy Patients treated with Chaulmoogra Oil] *Arquivos do Serviço Nac de Lepra* Rio de Janeiro 1946, Dec, v 4, No 3, 352-63, 7 figs

For oral administration the pure oil was used and for intramuscular or intradermal injection the esters. The authors aimed at giving 100 cc in 10-30 weeks, after which a rest of 15-20 days was interposed. When a total of 300 cc is reached (in 40-100 weeks), 2-3 months are allowed to elapse before another course is started. In children the dose used is smaller, 1-2 cc once or twice weekly, at times 3 cc, and the course is 100-200 cc according to the tolerance.

A table is given showing the results in 679 cases of the lepromatous form. Of 101 receiving up to 100 cc of the oil, 95 were worse, 5 were unchanged and one was better; of 92 receiving up to 200 cc 76 were worse, 14 unchanged and 2 improved; 10 patients received more than 2,000 cc, of these 8 were worse, 2 were better. Altogether of the 679, 581 (85.5 per cent) were worse, 75 (11.04) were unchanged, and only 23 (3.4) had improved.

Of the other forms, non-characteristic and tuberculoid, nothing definite is said, and the results would be difficult to gauge seeing that spontaneous remissions are fairly common in them.

H Harold Scott

FLOCH, H Influence du traitement par l'huile de chaulmoogra sur l'évolution de la lèpre [Chaulmoogra Treatment and the Evolution of Leprosy] *Arquivos do Serviço Nac de Lepra* Rio de Janeiro 1946, Dec, v 4, No 3 257-70

This paper deals with an analysis of 358 leprosy cases treated "more or less" for periods of 3 to over 12 years, with Chaulmoogra oil, with a view to determining the most efficient method of using the remedy. The first table shows ages and sexes. Bacteriological examinations, given in Table II, showed lepra bacilli on the skin in only 7 per cent of 234 cases and none in the nose among 196 maculo-anaesthetic cases. In nerve cases, 1 of 34 was skin-positive only. On the other hand, 66 of 68 lepromatous cases were positive bacteriologically in skin leprosy. Chaulmoogra oil was given intramuscularly in varying total amounts and frequencies shown in another table, which brings out the important points that in maculo-anaesthetic cases given a total of over 300 injections, 60 per cent were benefited against 45 per cent in those who were not so treated. Among 34 nerve cases the progress was not influenced by the number of injections. In the lepromatous form, improvement was seen in 45 per cent of those receiving an annual mean of 40 to 50 injections, but in very advanced cases the percentage fell to 25-30 per cent, as is shown in a table. The importance of long regular treatment is also shown in a table, 40 per cent of lepromatous cases benefited by treatment over the full period, as compared with 21 per cent who improved with shorter periods of treatment. Thus the treatment is more effective when it is carried out regularly for long periods than it is with shorter periods and frequent interruptions. This is in accordance with other recent experience. In a final table, this is confirmed by the finding that 50 per cent of those regularly treated for a sufficiently long period improved as compared with only 27 per cent who had irregular treatment with long intervals, instead of regular weekly injections for a minimum of three years.

CHAUSSINAND, R. PARIS, C. & CROUGER, O. Essais d'un traitement ambulatoire de la lepre par la streptomycine émulsionnée dans les esters éthyliques de chaulmoogra. [Streptomycin with Chaulmoogra Esters in Leprosy?] *Bull Soc Path Exot* 1948, v 41 Nos. 9 10 573-8.

This paper records a trial of streptomycin and chaulmoogra esters in two cases of leprosy. The first was an advanced lepromatous case with numerous lepra bacilli in the nose and in nodules, and of about 7 years duration. Daily injection of 1 cm. chaulmoogra esters with streptomycin in doses rapidly increased from one-third of a million to two million U.S. were continued for 79 days when they ceased to be absorbed. During that period a total of 42 million of U.S. unit were given. A notable reduction of diffuse infiltration of the face and ears but not of other cutaneous lesions was noted, together with diminution of nasal lepra bacilli, but those in the nodules were unchanged. The improvement was not greater than with chaulmoogra esters alone in the period of treatment. A second case was therefore treated in the same manner. This patient had signs of cutaneous erythematous lesion of the lepromatous type with numerous lepra bacilli but no infiltration. It was hoped that streptomycin might be more effective in such a comparatively early stage. The treatment was continued for 86 days, during which 135½ million units of streptomycin were given together with chaulmoogra esters. Only a minimal modification of the cutaneous lesions was obtained and there was no diminution in the cutaneous lepra bacilli although a slight bacterial infection of the nose cleared up. As far as these two cases go there was no definite evidence of any effect of the large and costly streptomycin treatment. See also FAGER and ENICKSON in *Bullet* 1948 v 45 442, 615.] L. Rogers

SOMTA LIMA, L. & CASTRO LEMQUEIRA, G. de Tratamento e profilaxia da lepra pelas diamino-di-fenil-sulfona. Trial Treatment of Leprosy with Diamino-Diphenyl Sulphone. *Arquivos do Serviço Vac de Lepra*. Rio de Janeiro. 1948, Dec. v 4 No. 3 78-89 5 figs. on 23 pls.

The crucial test of all treatment of leprosy must be their results in lepromatous cases because tuberculous forms and many of the non-characteristic forms tend to retrogress spontaneously.

The author here put on record the result of the use of diamine and pristin. Diamine was given orally in capsules containing 0.375 gm for 6 weeks followed

by two weeks' rest. One capsule daily was given for 3-4 days, then two for the same period and after that three capsules, or 0.99 gm, for the daily dose. This drug was given to 38 patients, 12 in an advanced stage, 20 "moderate", and 6 incipient cases.

Promin was administered intravenously to 42 patients, 17 advanced, 23 "moderate" and 2 incipient, starting with 1 cc, and gradually increasing to 5 gm [so stated, but the strength of the solution is not mentioned]. The drug was given daily for 15 days, followed by 7 days' rest. The red cells were counted and the haemoglobin estimated every 10 days. The following criteria were observed for estimating results: 1 *Dermatological*—comparison of the cutaneous condition before and after and at intervals during the treatment. 2 *Histological*—comparison of the histo-pathological picture before and at intervals after. 3 *Bacterioscopic*—the numbers and characters of the bacteria in smears and sections of the skin lesions. 4 *Clinical*—the general condition, including the ophthalmological and the oto-rhino-laryngeal.

Each of these is recounted and discussed in detail and the results shown in an elaborate series of tables, but much more will be gathered from a study of the excellent photographs of patients before treatment and during and after the courses. The histological changes are also well shown by photomicrographs. The results may briefly be summarized thus: Of the 38 receiving diasone, all 12 in the advanced stage showed some improvement, 3 marked improvement, 8 were better and one slightly better, of the 20 "moderate" cases 5 were much improved, 10 improved, 3 slightly better, 2 were unchanged, and of the 6 incipient cases one was much improved and the other 5 improved.

With promin treatment: Of the 17 advanced cases, 6 were much improved, 9 improved, one remained unchanged and one was worse, of 23 "moderate" cases 7 were much improved, 10 improved, 4 slightly better, 2 remained unchanged, both the incipient cases were much improved. In other words, of the total 80, marked improvement was reached in 24, considerable improvement in 42, slight in 8, 5 remained unchanged and one only was worse. [The numbers in the text have been added wrongly.]

In their conclusions the authors state that the drugs are well tolerated by leprosy patients of any age and are free from danger, if ordinary precautions are taken, that the drugs are active, clinically and bacteriologically, in the treatment of this disease, though the extent of this activity cannot at the moment be stated definitely, that they act beneficially on the eye symptoms and on those due to affection of the nose and throat, and that they certainly exercise a bacteriostatic, and possibly a bactericidal action, and, finally, that they seem to be the most efficient of drugs at present known in the treatment of leprosy and that they should be more widely used.

FIGUEREDO, N & DESAI, S D The Importance of Home Visits in the Control of Leprosy in Bombay City *Leprosy in India* 1948, July, v 20, No 3, 149-52

In 1941 the importance of home visits to follow up leprosy cases was emphasized and in 1942 the Clinic of the Ackworth Leper Home appointed two trained health visitors for this purpose, as 30 to 35 per cent of the cases attending the clinic were ceasing to come. Moreover the examination of contacts was unsatisfactory, as was the separation of healthy children from infectious cases many of whom could not be accommodated at the Ackworth Home. Visits of the health visitors to overcome these deficiencies during 1943 to 1947 amounted to nearly 14,000 and included the examination of over 7,000 contacts with the discovery of 445 suspected or clear cases of leprosy. Moreover 159 out of 412 patients were induced to resume attendance at the Clinic, which

The contagiousness of leprosy is next discussed and a number of cases of accidental inoculation of the infection are quoted. Infection through contact is pretty certainly due to close and long association, so it is largely a "familial disease" with relatively low infectivity. The bed bug is a more likely carrier than the cockroach. The Nauru epidemic is quoted as an example of control by isolation only of the bacteriologically positive infectious cases, and South African experience as a demonstration of the much greater effectiveness of the modern plan of only isolating with effective treatment infectious cases coming forward in the early stages of the disease. The author concludes that "To-day, however, there remains no doubt that one can save energy and money by isolating only the malignant lepromatous and NOT the Hansenite [uninfective] patients"

McCoy, G. W. Leprosy Factors in Public Health Management. *Pub Health Rep* Wash 1948, Nov 19, v 63, No 47, 1522-6

This paper deals with the prophylactic measures, from the American point of view. The author first states that "We hope that by now the routine control procedure—isolation of all cases of leprosy regardless of the possibility that some patients may not be a menace to their associates—has been discarded as there is no substantial evidence that it aided in controlling infection." The value of promising therapeutic agencies (sulphones) first tried by G. H. FAGER and his associates, will, it is hoped, lead to earlier and more effective treatment. Only the lepromatous and mixed lepromatous and neural types are likely to be sources of infection and to require isolation. Neural and anaesthetic cases are relatively free from danger of transmitting infection and should receive the benefit of the doubt and not be compulsorily isolated. The tuberculoid sub-type is also unlikely to be transmitted.

In diagnosis it is pointed out that in nasal smears a few non-leprosy acid-fast bacilli may sometimes be found, but bundles of such organisms are of diagnostic value. Histological changes may be misleading unless lepra-bacilli are present. Cases with nerve symptoms who have never lived in a leprosy area, are very unlikely to be leprosy. The disease in the U.S.A. is only a problem in the southern Gulf of Mexico States. From the public health point of view, the author advises that no special consideration is required for non-communicable cases where transmission is unlikely, home isolation or general hospital care are recommended for any cases where transmission is unlikely, and special hospitals for communicable cases where spread is likely to occur.

ASHBEL R. & POLJAKOFF, A. In Vitro Cultivation of the Rat Leprosy Organism. *J Infect Dis* 1948 Nov-Dec v 83, No 3, 279-82, 1 fig

CHAUSSINAND, R., PARIS, C. & CROUGUE, O. Essais de traitement par la streptomycine de l'infection murine due au bacille de Stefansky [Trials of Streptomycin in Rat Leprosy]. *Ann Inst Pasteur* 1948, July, v 75, No 1, 92-4

The direct action of streptomycin on Stefansky's bacillus of rat leprosy cannot be tested because that organism has not been cultivated, but the preparation did not have any effect *in vitro* in altering the appearances of the bacilli or their staining properties. Further, rats inoculated with the rat leprosy bacilli which had been exposed to the action of streptomycin were readily infected in a similar manner, as with the untreated organism. The action of the preparation was then tried *in vivo* by treating 30 infected rats with streptomycin and keeping 15 more as controls. The treatment was commenced

two and a half months after inoculation when infiltration could just be detected at the site of infection. Doses of 4,000, 8,000 and 16,000 U.S. units respectively were injected subcutaneously every other day for two months and the rats were killed from two to seven months after commencement of the treatment but the lesions observed were similar in the treated and untreated rats. The drug was then given to another series of animals up to doses of 16,000 units as before but commencing two days after inoculation with rat leprosy bacilli again no differences were found in the degree of infection after two to seven months. A further test in the more resistant mice also gave negative results a total of 180 rats and 40 mice being tested. Streptomycin may therefore be classed as ineffective against *Streptomyces* bacillus of rat leprosy.

Eskimo Intestinal Parasites of Eskimos on Southampton Island Northwest Territories. A Preliminary Survey. *Canadian J. Pub. Health* 1948 Nov. 39 No 11 451-4

"A study of intestinal parasites among 85 Eskimos on Southampton Island, N.W.T., showed that 33 individuals or 34.7 per cent. were infected with the following parasites: *Enterobius vermicularis* (22 cases), *Diphyllobothrium* sp. and *E. vermicularis* (3 cases), *Diphyllobothrium* sp. (8 cases), *Endamoeba* (in 1 case), *Giardia lamblia* (1 case). The specimens examined were 83.3% stool and 71 faecal samples.

"A varying degree of blood eosinophilia up to 56 per cent. was found in 79 cases examined. There appeared to be no relation between the percentage of eosinophils and the parasitological findings recorded.

[Studies of *Schistosoma haematobium* Infections cured by Antihomalline] *J. Rev. Egyptian Med.* 1st 1943 Feb., v 26 No 2 66-71 [Recd 13 Dec 1948]

MALDONADO J F & ACOSTA-MATIENZO, Josefina. Biological Studies on the Miracidium of *Schistosoma mansoni*. *Amer J Trop Med* 1948, Sept., v 28 No 5, 645-57

The authors carried out experimental studies on the hatchability, longevity and infectivity of the miracidia of *S. mansoni*, under controlled laboratory conditions. The material used and the experimental procedure are described in detail.

Hatching—Few miracidia emerged in the first hour but on exposing the eggs to artificial light, hatching proceeded rapidly. Out of 1,971 eggs 1,660, or 83.6 per cent hatched out. Of these, 65 per cent did so during the first eight hours and 24 per cent in the following 16 hours. Thus in the first 24 hours, 89 per cent of the hatching was completed. During the second 24 hours, about 9.5 per cent hatched and the remaining 1.5 per cent hatched early on the third day.

Longevity—Percentage mortality rates among similar batches of miracidia kept from one to nine hours respectively were as follows—8.6, 13.6, 21.5, 34.9, 32.3, 60.9, 62.7, 74.7 and 100. The average span of life was between 5 and 6 hours. The longevity of miracidia which hatched in the first 24 hours was observed to be greater than that of miracidia which hatched after a long time.

Infectivity—Snails (*Australorbis glabratus*) were exposed to miracidia for varying periods after hatching and their infectivity was estimated on the basis of observed penetration or failure to find the miracidia in the vessels after exposure. Of 103 miracidia exposed to the snail immediately after hatching, 71.8 per cent penetrated. This proportion gradually decreased to zero within 8 to 9 hours of free life.

The sites of penetration were observed in a batch of 110 miracidia. Of these 66.3 per cent chose the head-foot organ, 27.3 per cent the tentacles and 6.4 per cent the mouth collar.

DA SILVA, J R. Contribuição ao estudo das formas evolutivas da esquistossomíase mansoni. [Contribution to the Study of the Clinical Evolution of Infestation by *Schistosoma mansoni*] *Rev. Brasileira Med.* Rio de Janeiro 1948, Nov., v 5, No 11 794-802, 5 figs. [23 refs.] English summary.

In the clinical study of schistosomiasis it is clear that the parasitic activity is all-important. To determine this, the viability or otherwise of ova passed in the faeces is not a reliable guide, but a study of the ova obtained by rectal biopsy is. Eggs thus obtained may be living or dead, if living they may be mature or immature, or may show altered development, and in gauging the results of treatment examination of the ova may show whether they have died shortly before, some time before and become calcified, or have left empty shells. The action of specific drugs is not, it is believed, upon the eggs themselves directly, but upon the female worms, preventing oviposition. Hence, rectal biopsy and examination of ova so obtained are of value in assessing the results

two and a half months after inoculation when infiltration could just be detected at the site of infection. Daily doses of 4 000 6 000 and 8 000 U. S. units respectively were injected subcutaneously every other day for two months and the rats were killed from two to seven months after commencement of the treatment, but the lesions observed were similar in the treated and untreated rats. The drug was then given to another series of animals up to doses of 16 000 units as before but commencing two days after inoculation with rat leprosy bacilli again no differences were found in the degree of infection after two to seven months. A further test in the more resistant mice also gave negative results a total of 190 rats and 40 mice being tested. Streptomycin may therefore be classed as ineffective against Stefansky bacillus of rat leprosy.

Hsu K. C. A Survey of the Helminths of Dogs in Chengtu, Szechuan. *Chinese Med. J. Shanghai* 1943 July 66 No 7 361-70 [19 refs.]

(1) A survey of the helminths of 169 dogs in Chengtu was conducted and every dog was found to be infested. The number of pieces of parasites harbored by each dog varied from 1 to 7.

"(2) The percentage of dogs harboring round worm was found to be 60.5 per cent. They were *Uncinostoma caninum*, *Ancylostoma* sp. and *Uncinaria stenocephala*. *Toxocara canis*, *Spurocercia sampso oleus*, *Diphylaria immitis* and *Thelazia callipaeda*.

"(3) The percentage of dogs harboring cestodes was 69.7 per cent. They were *Taenia hydatigena*, *Diphyllobothrium* sp. sens. and *Diphylidium* sp. novum.

(4) The percentage of dogs harboring trematodes was 8.4 per cent. They were *Clonorchis sinensis*, *Paragonimus* spp. *Metagonimus yokohamae* and *Microstomum* sp.

performed on April 12th The dura was adherent to the posterior portion of the third middle frontal convolution and on the surface of the inferior frontal convolution a number of nodules, from pin-point to 2 mm in diameter, were observed Biopsy showed *S japonicum* ova There was immediately some improvement and this continued after three courses of stibophen (of 14 injections each with 5 ml as the maximum dose), however, he had several Jacksonian fits By May 20th 1947, the only residue was minimal aphasia No schistosome ova were found elsewhere in this patient

Case 2—An ex-service man, aged 22, with service in Leyte, gave a history of attacks of unconsciousness with left-sided twitchings, preceded by numbness of the left knee and headaches He was first seen on December 22nd, 1946 The subsequent seizures all involved the right side and he did not lose consciousness On examination between attacks he had slight weakness of the right grip, some incoordination of movement on the right side, a positive Romberg sign, and a tendency to adduct the right leg when walking

At craniotomy on February 25th, 1947, a fronto-parietal flap was made on the left side The posterior portion of the dura was adherent and yellowish-white masses of 2.5 mm were seen on the underlying convolution These were resected and *S japonicum* ova were found as in the previous case The patient was aphasic after the operation but recovered slowly He was given a course of stibophen starting on March 19th and by May 20th he was free of all neurological signs

Dr G M SAUNDERS, in a personal communication to the authors, reported two similar cases in which neurological localizing signs developed and craniotomy was performed, in one case with complete relief of symptoms, in the other with only partial Stibophen was also given when schistosome ova were demonstrated in the biopsy

In a discussion, in which the authors describe the life cycle of the worm, they note that cerebral complications are more common in the third stage of the disease than earlier Quoting CARROLL (*loc cit*) they state that the symptoms are usually somewhat different at the two stages Within the first 6 months of infection, there is usually drowsiness followed by coma and incontinence There may be signs of pyramidal tract involvement with weakness, spasticity, exaggerated reflexes, an extensor Babinski's sign, a high eosinophilia, and fever The symptoms tend to subside with the cessation of fever On the other hand, in the third stage, Jacksonian convulsions and hemiplegia are more common

The authors point out that patients with cerebral schistosomiasis very frequently give no history suggesting the early manifestations of the disease and the diagnosis is often dependent on the biopsy findings They consider that craniotomy is indicated as well as medicinal treatment, stibophen for preference

of treatment in some of the cases referred to ova obtained by rectal biopsy several months after treatment, were found to be still viable, clearly the treatment had been ineffectual.

H. HAROLD S. &

GELFAND M. & ROSS, W. F. The Diagnosis of Schistosomiasis by Rectal and Vesical Snips based on 150 Autopsies. *J Trop Med & Hyg* 1949 Jan. v 52, No 1 12-15

In S. Rhodesia MEXNER ROSS & BLAIR [this Bulletin 1948, v 43 791] have shown the superiority of rectal biopsy over the use of Weller's scraper in the diagnosis of rectal schistosomiasis. GELFAND [this Bulletin 1949 v 40 56] has demonstrated, post mortem, the efficacy of the examination of snips from the bladder in the diagnosis of *S. haematobium* infestations. In the present paper the diagnostic value of examination (post mortem) of snips from the bladder and from the rectum is further demonstrated. The conclusion is reached that biopsy from the bladder or rectum is warranted in clinical practice to establish a diagnosis of schistosomiasis. The authors supply the following summary —

- (1) A comparative study is made of 150 cases of schistosomiasis in which bladders and rectums were removed at post-mortem, snips being taken from these organs prior to their digestion in caustic potash.
- (2) The bladder snips were positive for *S. haematobium* in 80 per cent. of known cases of *S. haematobium* infection and the rectal snips were positive for *S. muroni* in 52 per cent. of known cases of *S. muroni* infection.
- (3) *S. haematobium* infection was diagnosed by rectal snip in 60 per cent. of cases.
- (4) These results confirm the value of vesical snips in the recognition of *S. haematobium* in bladder infestations and also the relative frequency in which *S. haematobium* infections may be recognised by rectal snips.
- (5) The results also confirm our previous experience that pure *S. muroni* infections are extremely uncommon in South Central Africa.

A. R. D. ADAMS

CHANG T. H., SMITH G. W., RIESSENMAN P. R. & ALSTON E. F. Cerebral Granuloma due to Schistosomiasis. *J Amer Med Ass* 1948, Jan. 1 v 138 No. 4 230-38 7 figs. [Ref. in footnotes.]

The authors were able to collect references to 23 cases of cerebral schistosomiasis prior to 1946 from 1946 onwards 15 additional cases including 4 by CARROLL [this Bulletin 1946 v 43 1047] and 6 by TILLYMAN [ibid 1947 v 44 600] have been reported. Of these 38 cases, in 29 the diagnosis was presumptive, on clinical evidence combined with pathological bowel findings, in 5 it depended on biopsy findings and in 3 on autopsy. In 3 cases *Schistosoma haematobium* was the parasite concerned and in 33 *S. japonicum*. In no case were *S. muroni* eggs found in the brain.

The authors report two further cases —

Case 1—An ex-service man aged 26 who had been on Leyl was seen on August 13th, 1943 with weakness of right arm and leg, dysphagia, blurring of vision, weakness of the right facial nerve and a low-grade fever all of a few days duration. By September 7th the weakness of the limbs had improved slightly but he was suffering from severe headaches. Hyperaesthesia and hyperreflexia were noted. He had a 1 per cent eosinophilia. By April 1946 there was further improvement in the paresis and hyperaesthesia, but the patient had developed complete motor aphasia. A craniotomy was

performed on April 12th. The dura was adherent to the posterior portion of the third middle frontal convolution and on the surface of the inferior frontal convolution a number of nodules, from pin-point to 2 mm in diameter, were observed. Biopsy showed *S japonicum* ova. There was immediately some improvement and this continued after three courses of stibophen (of 14 injections each with 5 ml as the maximum dose), however, he had several Jacksonian fits. By May 20th 1947, the only residue was minimal aphasia. No schistosome ova were found elsewhere in this patient.

Case 2—An ex-service man, aged 22, with service in Leyte, gave a history of attacks of unconsciousness with left-sided twitchings, preceded by numbness of the left knee and headaches. He was first seen on December 22nd, 1946. The subsequent seizures all involved the right side and he did not lose consciousness. On examination between attacks he had slight weakness of the right grip, some incoordination of movement on the right side, a positive Romberg sign, and a tendency to adduct the right leg when walking.

At craniotomy on February 25th, 1947, a fronto-parietal flap was made on the left side. The posterior portion of the dura was adherent and yellowish-white masses of 2.5 mm were seen on the underlying convolution. These were resected and *S japonicum* ova were found as in the previous case. The patient was aphasic after the operation but recovered slowly. He was given a course of stibophen starting on March 19th and by May 20th he was free of all neurological signs.

Dr G. M. SAUNDERS, in a personal communication to the authors, reported two similar cases in which neurological localizing signs developed and craniotomy was performed, in one case with complete relief of symptoms, in the other with only partial. Stibophen was also given when schistosome ova were demonstrated in the biopsy.

In a discussion, in which the authors describe the life cycle of the worm, they note that cerebral complications are more common in the third stage of the disease than earlier. Quoting CARROLL (*loc cit*) they state that the symptoms are usually somewhat different at the two stages. Within the first 6 months of infection, there is usually drowsiness followed by coma and incontinence. There may be signs of pyramidal tract involvement with weakness, spasticity, exaggerated reflexes, an extensor Babinski's sign, a high eosinophilia, and fever. The symptoms tend to subside with the cessation of fever. On the other hand, in the third stage, Jacksonian convulsions and hemiplegia are more common.

The authors point out that patients with cerebral schistosomiasis very frequently give no history suggesting the early manifestations of the disease and the diagnosis is often dependent on the biopsy findings. They consider that craniotomy is indicated as well as medicinal treatment, stibophen for preference.

JOYEUX, C. Les phénomènes d'immunité dans les hélmintoses considérés chez les cestodes de l'homme. (Immunological Problems in Helminthosis Infections with special reference to Cestode Infections in Man. *Med. Trop. Marseille*, 1943, July-Aug. Sept.-Oct. 8 No. 4 463-70 [77 refs.]

Joyeux discusses various aspects of natural immunity and acquired immunity in relation to helminth infections in general and then considers these phenomena in certain cestodes of medical interest. They are discussed under the headings, large and small cestodes in the light of a previous suggestion that the size of helminths may be a factor in determining the saturation point in helminth infections. In other words the protection given to a host against acquiring an unlimited number of helminths owing to continuous exposure to infection.

Large cestodes.—Premunition is especially evident in the case of *Taenia saginata* and *T. solium* in which infections with a single worm are the general rule though on rare occasions multiple parasitism has been observed. In one case of the latter kind, the worms were reduced in size and the number of segments was less than normal. *Diphyllobothrium latum* differs from the Taenid cestodes in that it is not restricted to the human host and commonly occurs as a multiple infection. Moreover there is some evidence that this worm induces an immunity of kind more resembling true acquired immunity than preunition. In infestation with the related non-human pseudophyllid *D. crassum* and *Ligula intestinalis* preunition is absent in the former but present in the latter. It is concluded that zoological affinities are unconnected with protection phenomena in the cases cited.

Small cestodes—It is known that mice are protected by the first infection with *Hymenolepis nana fraterna*, from subsequent infections with this species, but the human form of this parasite, *H. nana*, apparently induces no such response in the human host, judging from the enormous numbers of worms which have been found and which must have been acquired in successive infections. It is suggested that the difference in the volume of the human intestine from that of the rodent may be a contributory factor, and this recalls the idea of a "saturation point" previously postulated. *H. diminuta* occurs in the intestine of rats in fair numbers but premunition has been demonstrated in this infection, so that it is necessary to invoke the probability of a simultaneous ingestion of a number of larval stages, this is facilitated by the fact that the intermediate host often harbours several larvae.

In conclusion, the author sums up that in addition to natural immunity ("spécificité parasitaire"), premunition and acquired immunity are represented in certain helminthic infections, but the manifestations of the latter are sometimes inexplicable and do not conform to bacteriological conceptions of immunity.

J J C Buckley

OBRADOR, S. Clinical Aspects of Cerebral Cysticercosis. *Arch Neurology & Psychiatry* 1948, Apr, v 59, No 4, 457-68

Cerebral cysticercosis is common in Latin America. In Mexico ROBBS reported 25 cases in a series of 100 cases of cerebral tumour and in Chile, ARANA and ASENJO [this *Bulletin*, 1945, v 42, 908] reported 25 in a series of 202 cases of intracranial tumour. The author collected 17 cases during 5 years of neurosurgery in Mexico, of these 10 were confirmed at autopsy.

Cerebral cysticercosis can be classified as follows—

- 1 Cortical
- 2 Ventricular (a) Isolated, (b) Multiple
- 3 Basilar Predominantly in (a) region of the cisterna magna, (b) cerebello-pontine angle, (c) anterior and middle fossae
- 4 Mixed general and diffuse

The main symptoms of cerebral cysticercosis fell into four groups, epileptiform attacks, signs of increased intracranial pressure, mental disturbances, and loss of vision, according to the localization of the cysticerci. There is often pronounced cortical atrophy, this and other observations make the author consider the possibility of some "toxic" action of the cysticerci.

The course of the disease is sometimes rapid, especially in children, with "fever, headaches, convulsions, vomiting and other acute and generalized neurologic signs." Or it may be irregular with intervals as long as 20 years between the appearance of different signs. More characteristically there are irregular and diverse neurological symptoms of a slowly progressive nature.

X-ray study of the skull gives both non-specific evidence, mainly evidence of increased pressure, and specific evidence, multiple diffuse calcifications. These were observed in one-third of the author's cases. Rarely, the cysts produce erosions of the bone. Encephalograms and ventriculograms may contribute to the diagnosis. e.g. hydrocephalus associated with cerebral atrophy is fairly typical of cysticercosis. Contributory evidence may be obtained by the demonstration of calcified cysticerci in other parts of the body.

Contrary to the experience of the British school, the author has found valuable evidence from the cerebrospinal fluid. [In a footnote it is stated that the section on the cerebrospinal fluid was written by Dr D NIETO from all his own 27 cases.]

The non-specific changes in 27 cases consisted of an increase in the cellular count 15 to 100 per cmm with eosinophils varying from 0.5 to 33.0 per cent,

an increase in total protein up to but rarely above 100 mgm. per 100 ml. an increase in globulin and a decrease in the glucose content to below 50 mgm. per 100 ml. The Wassermann reaction was negative.

The specific indication is given by the complement fixation test with an alcoholic extract of cysticerci from the pig. The reaction is done on the same lines as the Wassermann reaction and in the author's 27 cases 2 were positive with 1 ml. 10 with 0.5 ml. and 15 with 0.2 ml. (The contrast between British experience, of cysticerci of Asiatic origin and the Latin American experience suggests that either the latter are not reporting the milder cases of cysticercal epilepsy so commonly encountered here or we are failing to diagnose very severe cases with signs of cerebral tumour or with predominantly psychotic symptoms. The milder epilepsy cases would not of course come into the hands of neurosurgeons. On the other hand it is possible that we are not paying enough attention to the cerebrospinal fluid in suspected cases.)

A full discussion.

SCHLANGER, P. M. & SCHLANGER, Henriette. Hydatid Disease and its Roentgen Picture. *Amer. J. Roentgenol. & Rad. Diag. Therap.* 1948 Sept., v 60 No 3 331-47 46 figs. [41 refs.]

To obtain the full value from this paper it will be necessary to refer to it in the original, since there are 48 excellent diagrams around which the paper is written. The authors have studied 130 cases of hydatid disease and they have added diagrams from Professor B. N. Calcagno's series of 350 cases.

The order of frequency of the localization of primary hydatid cysts is the liver (55 to 65 per cent.) the lung (17 to 24 per cent.) the bones the kidney and the spleen but practically any organ may be involved.

The liver cyst is the only one that is frequently calcified. Calcification does not indicate the death of the *Echinococcus* nor does it preclude infection at a later date but the authors have never seen a calcified cyst enlarging. The X-ray appearance may be that of a completely calcified round or oval mass or of a rounded reticulated shadow with or without a sharply defined segment of a circle at one part of the periphery. The liver is always enlarged, the right side of the diaphragm is raised, often divided into two arches, and its movement is limited. Cysts bulging from the lower surface of the liver often show a crescentic-like displacement of the barium-filled hollow viscera. Infected cysts usually show a fluid level. Ruptured cysts give a variety of appearances according to whether they have ruptured into the bronchial tree (reactive pneumonia) into the duodenum via the biliary duct directly into the digestive tract (reflux of barium into the cyst cavity) into the peritoneum, or through the skin.

Cysts occurred in the lungs in 22 per cent of the authors' cases. They were usually of considerable size and caused a bulging of the thoracic cage, but no erosion of the ribs is seen in extra-pulmonary cysts. They often lose their round shape and become polycystic. They do not usually calcify. Diagnosis is best made by a bronchogram, the bronchi and bronchioles appear as the fingers of a hand grasping the tumour, and the smallest bronchioles may be obstructed and end in a point. Rupture can sometimes be foretold by the appearance of pericystic emphysema. Clinically this is associated with slight haemoptyses.

There were 4 cases of bone hydatid in the authors' series and 30 in Professor Calcagno's. The bone is "blown up and riddled with cavities", there is no reparative reaction in the bone. Cysts of the spleen and kidney are difficult to differentiate clinically, but can usually be diagnosed by X-rays. Sometimes they are calcified. Cysts of the abdominal cavity are usually secondary to a ruptured liver cyst. The rupture may easily escape diagnosis at the time. After an interval, multiple cysts develop. Clinically the abdomen feels like a sack of potatoes and X-rays show innumerable "rounded shadows of the same density as the kidney".

PRAT, D. Complicaciones y secuelas del quiste hidático. Es la hidatidosis una afección benigna como se le ha considerado hasta hace poco? [Complications and Sequelae of Hydatidosis. Is this so Benign an Affection as it has been regarded until recently?] *Archivos Internac de la Hidatidosis* Montevideo 1947, Dec, v 7, Nos 1/2, 15-26, 5 figs

Though this article contains little, if anything, really new, it will serve a useful purpose if only it succeeds in impressing upon Uruguayan people in general that hydatids are not the benign, almost negligible, infestation to which they have paid but scant attention. The author quotes cases and gives illustrations of specimens from autopsies in which a neglected hydatid of the liver, for example, has led to an obstinate, even permanent, fistula or to rupture into the lung which could only be cured by the dangerous operation of lobectomy.

HALAWANI, A, NOR-EL-DIN G & SHAKER M. An Investigation of a Localised Epidemic of Acute Hookworm Disease. *J Roy Egyptian Med Ass* 1944, Aug, v 27 No 8 294-302 [11 refs] [Recd 13 Dec, 1948]

KYLE L H, MCKAY, D G & SPARLING, H J, Jr. Strongyloidiasis. *Ann Intern Med* 1948, Dec, v 29, No 6, 1014-42, 9 figs [52 refs]

A fatal case of *Strongyloides stercoralis* is presented. The filariform larvae were found in the usual locations and in addition were found in the myocardium, lungs, trachea, liver and gall-bladder.

The clinical manifestations of this infection are variable but in general they include abdominal pain, alternate diarrhoea and constipation, cough, dyspnea and hemoptysis.

Treatment with various drugs produces variable results. The best treatment to date is probably found in the use of gentian violet, given orally at first. If the infection is not cured by oral administration, intraduodenal and possibly intravenous administration should be tried.

SCHNECK G O & SCHULZE BUSCHOFF H. Synthetisches Ascaridol, eine neue Möglichkeit der Spulwurmbehandlung. [Synthetic Ascaridol in the Treatment of Ascaris Infestation.] *Deut med Woch* 1948 Aug 13 v 73 Nos. 29/32, 344-4 1 fig. [10 refs.]

Though ascaridol was isolated many years ago as an active principle of oil of chenopodium, constituting as much as 60 and even 80 per cent. of a good sample attempts to synthesize it have until recently met with no success. Now this has been done by the catalytic action of chlorophyll on α -terpenes in the presence of light resulting in the incorporation of oxygen as shown in the accompanying formula

The product is found both chemically and physically to be identical with the natural one. The relative toxicities were tested on mice and were found to be almost the same: the minimal lethal dose of the natural product being 0.157 gm./1000 gm. mouse and the absolute lethal dose 0.1 gm., whereas the relative amounts of Schneck's synthetic product were 0.16 and 0.2 gm. Tested on *Taenias* both the two were equally vermifugal.

Twenty-five human cases, all in adults whose ages ranged between 15 and 60 years are recorded (in tabular form) of its use in the following way: A castor oil or saline purgative in the evening; the next morning two capsules each containing 0.2 gm. of the ascaridol were given at 8 a.m. and a third at 8.30 a.m., 0.6 gm. in all. Breakfast at 10 a.m. consisting largely of vegetables and at 11 a.m. a castor oil purge. On the three succeeding days a dose of Carlsbad salts is given. One man of 42 years, expelled 496 ascarides and all appeared to be dead. The dosage for children is set down as: 3-year-old 0.1 gm., 3-4 years 0.2 gm., 5-6 years 0.3 gm. and 6-12 years 0.45 gm. These are the total dosages. In many cases a follow-up reveals no more passing of ova, but it is advised that if the treatment needs to be repeated an interval of 14 days should be allowed to elapse. No untoward side-effects have been reported or observed.

SCHUBERT R. Erfahrungen mit dem synthetischen Ascaridol Schneck. [Experiences with Synthetic Ascaridol "Schneck." *Deut med Woch* 1948 Aug. 13 v 73 Nos. 29/32, 344-5]

This author has tried the synthetic ascaridol prepared by Schneck on 35 patients with ascariasis. He reports very little success on his first trial: in six only were ova seen after the treatment and these cleared finally though oil of chenopodium had been given without effect previously. One patient had to have a second course of treatment.

OLIVER-GONZALEZ, J, SANTIAGO-STEVENSON, D & HEWITT, R I Treatment of Six Cases of Ascariasis in Man with 1-Dioethyl-Carbamyl-4-Methylpiperazine Hydrochloride *Southern Med J* 1949, Jan, v 42, No 1, 65-6

"Six patients infected with *Ascaris lumbricoides* were treated with 1-dioethyl-carbamyl-4-methyl-piperazine hydrochloride ('hetrazan'), at 2 mg per kg given three times during a twenty-four-hour period at eight-hour intervals. All worms were apparently removed from three patients. The majority of worms were removed from the remaining three patients, as demonstrated by egg count reductions after treatment of 83.4, 91.3 and 99.5 per cent, respectively. Living worms were passed in all cases. The compound produced no toxic effects in the doses used."

RABEE, A A Abdominal Section for Intestinal Obstruction due to 2005 *Ascaris* Worms *J Roy Egyptian Med Ass* 1943 Sept v 26, No 9 325-6 [Recd 13 Dec, 1948]

Report of a case

BRUMPT, E Filarioses et éléphantiasis [Filariasis and Elephantiasis] *Liber Jubilaris J Rodhain (Soc Belge Med Trop, Brussels)* 1947, Dec, 103-20

To explain the absence or rarity of microfilariae in patients suffering from elephantiasis, it would be necessary (i) to accept Manson's view that the recurrent attacks of fever had killed the adult filariae this is not very probable because, among healthy carriers, the worms persist in spite of more or less frequent attacks of fever, due for example to malaria, or (ii) to put forward the hypothesis that there is an antagonism in individuals between the conditions favourable for the evolution of the filariae and the development of elephantiasis. Now, such an antagonism would be curious since it would mean that, among a whole population of carriers of microfilariae, only those suffering from elephantiasis had any natural immunity against filariae or (iii) that a large percentage of sufferers from elephantiasis have acquired over a long period an active sterilizing immunity this prevents the evolution of millions of infective larvae by which they are inoculated in the highly endemic areas where 25-30 per cent of vector mosquitoes are infected.

However, from all the epidemiological observations of *W bancrofti*, we can conclude with certainty that elephantiasis is due to this filaria, the geographical distribution being the same. The association of bacteria for the production of elephantiasis is unnecessary.

All the research concerning *W malayi* shows a striking parallel between the incidence and abundance of microfilariae in a given population and the number of cases of elephantiasis. The aetiological rôle of this filaria is therefore well established.

Recent experience among American troops in the endemic areas in the Pacific indicates that the rôle of "*W pacifica*" as the cause of elephantiasis, whether it is a separate species or a geographical race of *W bancrofti*, cannot be doubted.

On the subject of the pathogenesis of the lesions produced by *Onchocerca volvulus*, it is not possible to bring definite evidence as to whether they are caused by mechanical action or a toxin. It is difficult to attribute to the microfilariae of this parasite, which are found in small numbers in the lymphatic glands, any more than one does to those of *W bancrofti* a rôle of blocking the

blood vessels. On the other hand if one allows a toxic rôle to this parasite it is difficult to account for the fact that only a small percentage of cases show lesions further microfilariæ may be found in the conjunctiva without causing any interference with vision. One must conclude that either some persons are particularly susceptible or that some strains of *O. rostralis* are particularly pathogenic.

ZANETTI, V. Traitement de certains phénomènes allergiques d'origine filarienne par auto-allergène urinaire. [The Treatment of certain Allergic Phenomena of Filarial Origin with Auto-Allergens from the Urine.] *Soc. Bole. de Méd. Trop.* 1943 June 30, v. 28 No. 2, 237-62.

Cutaneous allergic manifestations oedema, pruritus, urticaria and lichenification and thickening of the skin are mainly associated with *Onchocerca rostralis* infection but may occur with *Loa loa*. They occur mainly in Europeans who have been repeatedly subjected to infection over long periods and they can be extremely troublesome. The pruritus is sometimes unrelenting and interferes with sleep. This results in violent scratching with subsequent secondary infection.

The author decided to try inoculation by auto-allergens obtained from the urine of the patient. The allergens were prepared by the method of BARRIS and ORIEL (*Brit. Encyclopaedia of Med. Pract.*, v. 3) 229.

At first he had doubtful results but he obtained a very good result in a non-filarial patient allergic to insect bites, with very small doses of allergen. This made him realize that previously he had used too large doses.

He subsequently adopted the technique of giving four test doses into the skin of the anterior surface of the forearm, in strength of 1 in 1,000, 1 in 10,000, 1 in 100,000 and 1 in 1,000,000 sufficient to produce a wheal of 7 mm. in diameter. The results were read in 24 to 48 hours. Round raised reddish papules of 4 mm. in diameter were produced which disappeared after another day or two. Dilutions of 1 in 100,000 were uniformly positive and 1 in 1,000,000 were doubtful.

The treatment consisted of 10 subcutaneous injections, 1.03 ml. 1 in 1,000,000 dilution once a week. Improvement commenced after the first injection and continued. The desensitization usually lasted six months or so but another injection re-established it. In the pruriginous forms there was sometimes a slight exacerbation after 36 hours preceding the improvement. The author adopted the above dosage as a standard often without preliminary testing. With larger doses there was frequently an oedematous reaction.

ALVAREZ CRISTO, J. *Dracofilaria immitis*. Investigación en perros de la ciudad de Guayaquil. [*Dracofilaria immitis*. Investigation of Dogs in the City of Guayaquil.] *Rev. Ecuatoriana de Hig. y Med. Trop.* Guayaquil 1944 Apr. 1, v. 1 No. 1, 199-202, 1 fig. English summary.

HAWKING, F. & SEWELL, P. The Maintenance of a Filarial Infection (*Leishmanoides cavia*) for Chemotherapeutic Investigations. *Brit. J. Pharmacol. & Chemotherapy* 1948, Dec. v. 3 No. 4, 283-86, 4 figs. on 7 pl. 31 refs.]

Cotton rats naturally infected with the filarial worm *Leishmanoides cavia* have been used by CHLAKOVSKY and colleagues in testing possible chemotherapeutic agent in this infection. [this Bulletin 1944 41 7-9 1945]

v 42, 136] WILLIAMS and collaborators successfully transmitted *L. carini* to cotton rats and white rats by the tropical rat mite *Liponyssius bacoti* and described the method of rearing the vector in the laboratory, and also made important observations on the life cycle of the filarial worm *L. carini* [*ibid*, 1946, v 43, 663, 1080, 1948, v 45, 629] SCOTT and his colleagues infected cotton rats and white rats with the same filarial parasite through contact of clean animals with cotton rats already infected, and made important observations on the rate of growth and maturity of *L. carini*. Later that author described the production of quantitative filarial infections in the cotton rat with much technical detail so that accurate chemotherapeutic studies became possible [*Amer J Trop Med*, 1946, v 26, 849, this *Bulletin*, 1947, v 44, 447, 839, 840]. In Britain, BERTRAM and colleagues have also made useful contributions on the same subject [*ibid*, 1946, v 43, 1197]. The experiments described by the present authors owe much to the generosity of American workers for demonstrating their methods and providing infective material. Mites were bred on sawdust in jam jars kept in an insectary with a day-old rat or mouse to feed on. The mites were then transmitted in the sawdust to sterile tanks and allowed to feed on infected cotton rats with microfilariae in their blood. Fresh young cotton rats were then introduced to the tanks for the infected mites to feed on after removal of the infected animals. About 8 weeks later, a drop of tail blood was examined, after staining, for the presence of microfilariae. Adult worms are found in the pleural cavity and mediastinum after a time, but may be absent, suggesting that spontaneous cure has occurred. The cotton rat nevertheless appears, from the literature, to be the best experimental animal available. To estimate the value of chemotherapeutic agents, examination of adult worms and microfilariae should be made since various classes of drugs affect the different developmental stages of the worm in different ways. It appeared that six daily doses of drug given intraperitoneally was a suitable method of treatment. Six days after the last dose, the rat was killed and examined for adult forms and microfilariae. The activity of antimonials and arsenicals in this infection, as described by other authors, was confirmed.

WANSON M. Notes sur le comportement de *S. albivirgatum* Wanson et Henrard [A Note on *Simulium albivirgatum* Wanson and Henrard] *Ann Soc Belge de Med Trop* 1948, June 30, v 28, No 2, 279-85

Simulium albivirgatum is widely distributed in the Belgian Congo, coming third in frequency and distribution after *S. damnosum* and *S. griseicollis*. It attacks animals, birds and man. Some notes are given on its habits and a table shows the monthly collections for 1946 and 1947. Numbers are highest for the dry months June to September and lowest in the wet months. This species attacks the lower parts of the body, not usually higher than the knee of a standing man.

At Léopoldville, 0.53 per cent of captured female *S. albivirgatum* were found to contain 'sausage forms' of *Onchocerca volvulus*. In 6,000 dissections no further development was observed. In the laboratory 362 females were reared and fed on infected volunteers. A number of these flies were killed, dissected and examined daily for nine days, and the natural findings were confirmed. No larvae of *O. volvulus* were seen in the head or mouthparts and the development in body cavity or thoracic muscles did not proceed beyond the 'sausage stage'.

BASCHCEV, J. C. Trichocephalosis y arsenicos organicos pentavalentes. [Trichocephalosis and Arsenical Compounds.] *Rev. A. de Med. Trop. y Parasit.* 1943 Sept.-Oct., v 4 No. 9 10 185-8.

The English summary appended to the paper is as follows:—

"The author reports on the action of Arsenical compound on *Trichocephalus* trichuris.

Five cases of Trichocephalosis were treated with Acetamidobenzoyl-xybenzyl-carbonic-acid mixed with sodium carbonate (Content of a tablet Arsenic 0.25 Gm., Carbonate 0.15 Gm. Dose Up to 123 Pils., 0.008 Gm. for each pound of weight for 10 days).

Administering 4-carbamino-phenyl-carbonic acid also mixed with sodium carbonate (Arsenic 0.25 Gm. Carbonate 0.15 Gm.) the author treating 14 cases reports a 64% cure.

DEL CAMPO VÁSQUEZ, M. & MALHOTRA, L. Incidencia de triquinosis en gatos de la ciudad de México. [Trichinosis in Cats in Mexico City.] *Rev. Inst. Salubridad y E. enfermedades Trop. México* 1943, Ma. v 9 No. 1 31-4.

The English summary appended to this paper is published in the *Bulletin of Hygiene* 1943, v 23, 85A.

GRUBER, O. F. Effects of Digestion and Refrigeration on the Ability of *Trichinella spiralis* to Infect Rats. *J. Parasitology* 1943, Oct., v 34 No 3 304-5.

The effects of digesting *Trichinella* cysts for periods of 4, 8 and 12 hours in a solution of 1 per cent. pepsin and 0.5 per cent. hydrochloric acid (pH 2.0) together with varying periods of refrigeration at 5°C. were tested in relation to the subsequent infectivity of the larvae. One series of 12 rats was fed with 3,000 larvae per rat and a second series of 12 rats with 3,000 larvae per rat. Each rat was killed 24 hours after the infective feed and the larvae recovered from the intestine were counted. The results indicate that the infectivity of the larvae was not impaired by 4 to 8 hours of digestion nor by 24 hours of refrigeration but 12 hours of digestion resulted in a lowering of the percentage of worms recovered. Larvae exposed to 72 hours of refrigeration, however, showed a much reduced recovery rate even in combination with only a few hours of digestion.

DEFICIENCY DISEASES

CORKILL, V. L. The Poisonous Wild Cluster Yam, *Dioscorea d. nutans* Pax, as a Famine Food in the Anglo-Egyptian Sudan. *Ann. T. of Med. & Parasit.* 1943, Dec. 4th No. 34 278-87 pl. & map 17 refs.

"1. Following a locust visitation which destroyed much of the crops in the Fung area of the Sudan in 1939 some 12 wild tubers and roots were widely used as food.

"2. The most important was the cluster yam *Dioscorea dumetorum* Pax, presumed to contain the alkaloid dioscorine.

3. Cases of poisoning resulted from its use as a food although most communities soon evolved methods of detoxication.

"4. The yam was usually prepared either as a cooked whole vegetable or flour for making cakes, or as a porridge. Beer was also made from it.

" 5 Its nutritive value was mainly as a calorie food, but it also contributed most protein to the famine diet, and seems to have been the main antiscorbutic food, being thus analogous to the potato in parts of Ireland

" 6 Two closely related forms from Asia are referred to "

VELEZ BOZA, F. La alimentación y la nutrición en Venezuela [Food and Nutrition in Venezuela] *Rev Sanidad y Asistencia Social* Caracas 1948, Jan-Apr, v 13, Nos 1/2, 1-183, 22 pls, 8 charts & 2 maps English summary

KOENIGSFELD, E. G. H. & DESAI, V. G. Corneal Opacities among Children of a Railway Colony in the Dekkan *Indian Med Gaz* 1948, Aug, v 83, No 8, 383-7

Corneal opacities, affecting one or both eyes, were found in 20 (2.6 per cent) of 761 children examined. Fifteen of the twenty cases showed wasting and anaemia. No other signs of nutrition deficiency are recorded. Evidence of trachoma was present in only a small number of cases.

The authors conclude that malnutrition is the main aetiological factor, but are unable to incriminate any specific factors. *Dean A. Smith*

RAMALINGASWAMI, V. Nutritional Diarrhoea due to Vitamin A Deficiency *Indian J Med Sci* 1948, Nov, v 2, No 11, 665-74 [26 refs]

It is well known, particularly from animal experiments, that keratinizing metaplasia associated with vitamin A deficiency affects many epithelial structures. While ocular and dermal lesions have received much attention, diarrhoea as a manifestation of human vitamin A deficiency has seldom been recorded.

Twenty children with keratomalacia or Bitots' spots, skin changes, low plasma vitamin A levels and diarrhoea were treated with vitamin A concentrate. The diarrhoea was controlled within 48 hours on this treatment alone and as there was no evidence of infection nor of other nutritional deficiency (except possibly protein) it is concluded that the diarrhoea was part of the avitaminosis A syndrome. *Dean A. Smith*

HAMMOUDA, M. & NAGI, M. The Use of Pyridoxine in the Treatment of Egyptian Pellagrins *Acta Tropica* Basle 1948, v 5, No 4, 357-9, 1 fig

Loss of muscular power is frequently found in pellagrins and, unlike the classical features of the pellagrin symptom complex, dermatitis and diarrhoea, is not greatly improved by treatment with nicotinic acid.

Seven pellagrins were tested, before and during treatment, by means of a spring ergometer and it was found that pyridoxine (vitamin B₆) in doses of 50 mgm daily, by the intravenous route, rapidly restored muscular power. [Several clinical signs such as angular stomatitis, once thought to be essential parts of the pellagra syndrome, are now known to be due to a commonly associated deficiency—in the instance quoted, ariboflavinosis. The present evidence suggests that loss of muscular power may come to be regarded in the same way as due to an associated pyridoxine deficiency.] *Dean A. Smith*

TROWELL, H. C. Medical Examination of 500 African Railway Workers *East African Med J* 1948, Nov, v 25, No 11, 423-32 [29 refs]

The author points out that in many nutritional surveys only clinical material is collected, there is usually no reference to pathological studies, and this may lead to serious mistakes.

The frequency and incidence of liver disease (especially cirrhosis) of chronic nephritis and of chronic pancreatitis are decreased. DAVIES (this Bulletin 1947, 44, 1098) in a review of nearly 3,000 autopsies at Kampala, Uganda, 11 livers being examined by himself considers that these lesions can be traced back to an acute attack of severe malnutrition (kwashiorkor) in childhood. The present author thinks that there is clinical support for the view that malnutrition at this age may lead to certain permanent and incurable defects while the chronic inflammation of liver and pancreas is apt to lead to carcinoma. This work however requires to be extended and confirmed, as the real point at issue is whether these chronic lesions are really the result of malnutrition. There has been no detailed study of the enlargement of the parotids, which clinically appears to be part of the syndrome. The cause of the acute lesion is still unknown and it is uncertain if this begins in the liver or as DAVIES suggests (this Bulletin 1948, 45, 633) in the pancreas.

Judged by physique and strength of the dynamometer pull, a large proportion of Africans come within the normal range seen in Europeans, but a fair number fall below the standards set by other members of their own tribe and it is thought that the available evidence suggests that the latter group represent the effects of disease and malnutrition rather than a normal variability. At autopsy a large proportion show abnormalities of the liver, pancreas and salivary and ductless glands. Clinically a number show such signs as soft, brown hair, cracked skin, enlarged parotids, gynecomastia and enlarged livers. Many of these signs appear to have originated in an acute attack of malnutrition in childhood, but it is considered that more exact test of renal, pancreatic and hepatic function must be devised.

On the whole ordinary diseases were uncommon among railway workers although the evidence suggests a high incidence of respiratory infections probably due to overcrowding in the quarters, such infections being the commonest cause of death and absence from work. It is thought that vitamin deficiency did not materially reduce efficiency. The sign of malnutrition as detected in the African soldier (KIRKWOOD, 1947 unpublished data) and in the railway worker do not suggest any recognized vitamin deficiency but rather that malignant malnutrition had persisted. This was supported by pathological studies and explains why many of the signs did not improve on the general army diet.

The author considers that in certain districts of Africa a fair proportion of the population suffer from varying degrees of malignant malnutrition, have a disease which is progressive and incurable and can never give efficient work even on a perfect diet. Further their descendants will be small and nutritionally handicapped, while there can be little progress until the cause and course of this condition is recognized.

(Is malignant malnutrition the main cause of the small birthrate found in many parts of Africa?) C. F. SHOOTER

SALCEDO J. Jr, CARRASCO E. O., JONES T. R. & VALDIVIA, R. C. Studies on Beriberi in an Endemic Sub-Tropical Area. *J. Nutrition* 1948, 1, 10, 36, No. 5, 541-77. 23 refs.)

Beriberi rank second only to pulmonary tuberculosis as a cause of death in the Philippines, has been claimed over 3,000 lives in 1947 with a mortality rate of 13% per 100,000. Highly milled rice is the staple.

An attempt is projected to reduce the beriberi incidence in an area of high endemicity by artificial enrichment of the entire rice supply. This paper records the findings of a preparatory clinical survey. In all 12,004 persons were examined among whom 1,500 cases of beriberi were encountered.

No significant difference in the incidence of beriberi between the urban and rural populations was found. The individuals were grouped by age and physiological state. The group incidence, in descending order of frequency, was "expectant mothers", "nursing mothers", "other adults", "infants" (0-2 years) and "children" (2-15 years). Although there was a relatively low incidence in infants, mortality in this group was extremely high.

Estimations of thiamin were carried out in a one-hour urinary excretion after a 12-hour fast. The mean excretion in beriberi subjects was somewhat lower than in 65 apparently normal subjects, but there was no correlation between "fasting hour" thiamin excretion and severity of clinical manifestations.

The dietary records of all the individuals surveyed were kept for a nine-day period. The majority of the beriberi cases fell into the groups showing low dietary thiamin calorie ratios. Investigation showed that 15 per cent of the subjects washed their rice 4 times before cooking, 55 per cent 3 times and 30 per cent twice, all rice washings were discarded by over 80 per cent of the subjects.

The survey will be repeated after a trial period, enriched rice will be used

SPRUE

SUAREZ, R M, PEREZ-SANTIAGO, E, RODRIGUEZ-MOLINA, R, TORREGROSA, M V & BENITEZ-GAUTIER, C. Response of Tropical Sprue to Synthetic Pteroyltriglutamic Acid (Teropterin). *Bol Asoc Med de Puerto Rico* 1948, Sept, v 40, No 9, 235-40

Five sprue patients in Porto Rico were treated with Teropterin (pteroyltriglutamic acid). Four received 10 mgm intramuscularly and one 20 mgm daily, and all five responded in a clinical and haematological sense. The reticulocyte response was maximal even in one who was 88 years of age. One whose sprue was complicated with severe schistosomiasis and pronounced splenomegaly showed definite clinical and haematological response to a daily dose of 20 mgm. No deleterious effects which could be attributed to the triglutamate were observed. A daily dose of 10 mgm Teropterin which is equivalent to 6.3 mgm of folic acid, intramuscularly, is probably adequate in the treatment of sprue.

P Manson-Bahr

1 SUAREZ, R M & SPIES, T D. The Effectiveness of Vitamin B₁₂ in the Treatment of Tropical Sprue. *Bol Asoc Med de Puerto Rico* 1948, Aug, v 40, No 8, 199-209 [11 refs]

11 SPIES, T D & SUAREZ, R M. Response of Tropical Sprue to Vitamin B₁₂. *Blood* 1948, Nov, v 3, No 11, 1213-20, 5 figs

1 Six patients in Porto Rico suffering from tropical sprue were treated with intramuscular injections of vitamin B₁₂. In the first, a single injection of 10 mgm was given. In the second a second injection of 20 mgm was administered seventeen days later and a third of 25 mgm twenty-six days later. In case 3, a similar dosage was employed. The 4th patient received a single dose of 20 mgm, the 5th one of 4 mgm and the 6th two 25 mgm doses at twenty days apart. One patient did not respond to a single dose of 10 mgm and one other who received 4 mgm showed only a minimal reticulocyte response.

These responses were much greater when supplemented with folic acid or vitamin B₁₂.

No definite conclusions as to dosage or spacing were arrived at.

ii This paper appears to refer to five of the patients described above.

HAMID A. Cases of Sprue treated by Laparotomy. *Indian Med Gaz.* 1949 Aug., v 83 No. 8, 374-6

The underlying idea of performing laparotomy was to observe the effect of localized peritonitis acting as a counter-irritant. As the cases were typical, no stool or blood examinations were done. They were not improving on the orthodox treatments but the effect of operation was dramatic. The diarrhoea ceased and the patients did not have any motions for three or four days, nor did they develop tympanites.

The laparotomy was performed by a lower median incision, the intestines were gently massaged and a drachm of ether was poured in before the abdomen was closed. No relapses have so far been reported. In each case the illness had persisted for five months to one year. Two cases were in women of 23 and 25 and two were in men of 30 and 40 years respectively. P. *Mansam-Bahr*

HAEMATOLOGY

BARNES G. T. An Investigation into the Causes of Severe Anaemia in Fiji. *J. Trop. Med. & Hyg.* 1948, July, v 51 No. 7 133 p. 6 figs.

Forty-nine cases of severe anaemia are discussed in this report. Of these 28 (57 per cent) were in Indian women and 18 (37 per cent) in Indian males. Only a very occasional Fijian case was encountered.

Twenty could be classified as hookworm anaemia of a hypochromic type which responded satisfactorily to iron. Four of the patients fell into the group "very light" and light infestation which may be of no clinical importance. That anaemia-producing factors other than hookworm infestation exist is shown by the absence of correlation between the degree of anaemia and the intensity of infestation. Thus 41 worms were recovered from a patient with haemoglobin percentage of 31 and 5000 from another with haemoglobin percentage of 58.

Furthermore gastric analysis revealed achlorhydria in one and hypochlorhydria in seven others, suggesting that a deficiency of dietetic iron may be the predisposing cause of the anaemia. Other anaemia-producing factors are malaria in one and chronic blood loss from haemorrhoids in another. Both these conditions were considered of less importance than hookworm infestation and dietetic iron deficiency.

Among the males there was a single case of hypochromic anaemia not attributable to hookworms.

It has long been appreciated in Fiji that there exists a peculiar manifestation of severe anaemia among young Indian women. These are often women with a haemoglobin percentage of 20. Fijian women have a lower normal level of haemoglobin than the men and it is reasonable to assume that the explanation lies in the iron-deficiency of the Indian diet made more acute by the loss of iron by menstruation and parturition.

Of eleven Indian women tested five had hypochlorhydria and four others achlorhydria and only two gave gastric analysis curves within normal limits. The ages of the fifteen patients in this hypochromic group ranged with one

exception from 15 to 30 whereas idiopathic hypochromic anaemia in temperate climates is a disease of the fourth and fifth decades Hookworm ova were found in the stools of ten out of these fifteen Ankylostomiasis however could be assessed as a contributory cause, the obstetric factor being predominant Probably the label hypochromic (obstetric anaemia) is most satisfactory

Four cases of hyperchromic anaemia were seen in Indian women between the ages of 20 to 30 Each had been in childbirth a month or less before admission and showed in this respect a resemblance to hypochromic (obstetric) anaemias Clinically, in the degree of enlargement of liver or spleen, in the presence or absence of glossitis, there was nothing to distinguish the hyperchromic from the hypochromic patients The most important feature in the initial stages is the finding of erythroblasts in blood smears and an abnormally high indirect Van den Bergh reaction This disease is the tropical nutritional anaemia commonly affecting young native women in India

Dimorphic (obstetric) anaemia was found in six Indian females between the ages of 19 to 30 and in one Indian man It appears that pregnancy, childbirth and lactation also play a large part in precipitating this severe anaemia Diagnosis is suggested by finding a remarkable mixture of macrocytes and microcytes in blood smears, but the final verdict is determined therapeutically by combined liver and iron

Two cases were classified as hypoplastic anaemia, an Indian woman of 25 and an Indian male of 60 The anaemia was very severe in both, the haemoglobin being under 25 per cent and the red blood corpuscles under 1 million per cmm, the mean corpuscular volumes were 70 cm and 80 cm and colour indices less than unity

The outstanding feature was their resistance to treatment with full courses of liver, iron, blood transfusions and hydrochloric acid P Manson-Bahr

SUNDARAM, S K Folic Acid in Megalocytic Anaemias (with a Digression on Achylia Gastrica in Addisonian Pernicious Anaemia) *Indian J Med Sci* 1948, Nov, v 2, No 11, 680-86 [13 refs]

A series of 14 cases of megalocytic anaemia, some of them complicated with diarrhoea One was an undoubted case of sprue All were treated with a preparation of folic acid and a combination of folic acid and liver With the exception of two cases the results were uniformly good In some a soluble preparation was used for injection in doses of 1 to 5 cc anaphylactic reaction had to be avoided No therapeutic differences could be found between pure folic acid or folic acid combined with liver

VENOMS AND ANTIVENENES

BOQUET P & LEHOULT, Y Les méthodes actuelles de préparation et de titrage des sérums antivenimeux [Methods Used for the Preparation and Titration of Antivenin] *Rev d'Immunologie* 1948, v 12, Nos 3/4, 116-26, 2 figs [32 refs]

The development of the methods for preparing antivenene for therapeutic use is briefly reviewed The early preparations were made by Calmette by the injection of gradually increasing quantities of venom, and antivenene of low potency was obtained, but only after a long series of injections With the substitution of formolized venom a much more potent antivenene was obtained in a few weeks the effect of the route of injection of antigen, the interval

between injection and the addition of taploca calcium chloride and other substances was studied and the method of immunization devised to economize antigen in wartime are described. The antibody is associated with the globulin fraction of the serum proteins can be concentrated by ammonium sulphate precipitation and refined by enzyme digestion.

The method of testing the potency of antivenene are also reviewed. The author consider that Calmette's original method whereby mixtures of varying quantities of anti-venene with a constant quantity of venom are injected, gives quickly and easily an estimate of therapeutic value but it is laborious. Ipsen's method which has been used with success by other workers was used by the authors who obtained consistent results on the whole in rabbits and mice they emphasize the need for using mice of the same weight and maintained under the same conditions of temperature diet etc., during the test. The limitations of Ipsen's method are pointed out as well as those of an in vitro method based on flocculation.

GREER W. E. R. Arachnidism. Effect of Calcium Gluconate in Six Cases. *New England J. of Med.* 1949 Jan. 6 v 240 No. 1 5-8, (20 refs.)

Arachnidism, a definite clinical entity in medicine is reviewed, and 6 cases successfully treated with intravenous injection of calcium gluconate are discussed.

Arachnidism should be considered in indigenous areas in the differential diagnosis of the acute surgical abdomen. It may imitate appendicitis perforated viscus peritonitis or any other acute surgical emergency.

"The syndrome following the bite of *Latrodectus mactans* may give symptoms referable to many system of the body. Nervous cardiac renal pulmonary and cutaneous manifestations may be present.

Burning of the soles of the feet may be pathognomonic in arachnidism.

"One should be familiar with the clinical picture so that proper diagnosis is made and proper therapy instituted with avoidance of unnecessary surgical operation.

DERMATOLOGA AND FUNGUS DISEASE

NUSSF. ANDRADE R. Trombidiasis por *Nesochoragastria* *de Hoffmann* 1944 [Trombidiasis caused by *Nesochoragastria*, the mite *Hoffmann*, 1944. *Gac. Med. de Mexico* 1947 Aug & Oct 77 Nos 4 & 5 221-41 31 fig on pl. (81 refs) English summary]

In September 1944 the author observed 6 cases of dermatitis in family of 3 adults and 3 children in Mexico City. The parasite concerned was *Nesochoragastria* *de Hoffmann* larvae of which were found on the scalp of girl of three. The disease then spread to the other members of the family.

The disease can affect any part of the skin but attacks particularly the scalp, neck, back, shoulders, axillae and retro-auricular folds. The dermatitis is polymorphic and its forms include petechiae, hives, papules, vesicles and especially molluscoid elements. The prominent feature is itching, together with a burning sensation and constitutional symptoms—leucocytosis and eosinophilia occur. Differential diagnosis from many other skin conditions is required and this is discussed in some detail. The acute stage lasts for one to four weeks. The course is usually benign. Abscesses and moniliasis may occur as complications. The larvae are parasitic on hens and infection is therefore commoner in rural areas. Prevention consists of treating chicken-pens with DDT.

The condition responded rapidly to treatment with preparations having a benzyl benzoate base.

The monograph is illustrated with 4 sketches of the larvae and 27 photographs, illustrating the clinical condition and several other forms of dermatitis.

LATAPI, I. Carate o mal del Pinto. Clínica y diagnóstico diferencial. Comentario al trabajo del Dr A L Briceño Rossi. [*Differential Diagnosis of Pinta. A Comment on the Views of Dr Briceño Rossi*] *Medicina* Mexico 1948, Feb 10, v 28, No 549, 58-66.

The chief interest of this contribution lies in the discussion of Briceño Rossi's view that Cuban pinta is not the same as Mexican pinta. It appears that Rossi regards what has been called pinta or Mal del Pinto in Cuba as really a late manifestation of yaws or syphilis. León y Blanco maintains that the Cuban and the Mexican pinta are one and the same, because experimental inoculation of treponemata taken from these produces lesions indistinguishable from one another, and it is suggested that the early manifestations as seen in Mexico have passed unrecognized in Cuba. It is true that in 1944 material taken from a patient with pinta in Cuba, when inoculated into a human subject, produced syphilis, but that is explained by saying that the man suffered also from syphilis. León y Blanco has had the opportunity of studying the disease in both countries and is firmly of the opinion that they are identical. [Further study is needed to set all doubt at rest, it should be quite possible to inoculate a Mexican pinta subject with material from a Cuban patient and *vice versa* without the risk of inoculating syphilis at the same time. For previous observations by BRICEÑO ROSSI, see this *Bulletin*, 1944, v 41, 866, 867.] H Harold Scott

DUNCAN, J. T. The Epidemiology of Fungus Diseases. *Trans Roy Soc Trop Med & Hyg* 1948, Nov, v 42, No 3, 207-16 [21 refs].

In support of his thesis that a survey of fungus diseases in the British tropical colonies is long overdue, the author succinctly reviews with pertinent examples the results of recent studies in other parts of the world on the epidemiology of the dermatomycoses and the systemic mycoses. The need for providing special training in medical mycology and mycological methods for bacteriologists and pathologists stationed in the tropics is emphasized and the suggestion made that one way of meeting this need would be to include medical mycology as an elective subject in the curriculum for the Diploma of Tropical Medicine.

G C Ainsworth

DOWDING, Eleanor S. The Spores of *Histoplasma*. *Canadian J Res Sect E Med Sci* 1948, Oct, v 26, No 5, 265-73, 2 figs & 4 pls [14 refs].

The characteristic, terminally attached, spherical chlamydospores of the mycelial form of *Histoplasma capsulatum*, bear, on all parts of their surface,

Idi sore (diphtheritic desert sore)—This term should be confined to ulcers of diphtheritic origin the diagnosis being made bacteriologically and the condition treated with anti-diphtheritic serum administered by injection and applied locally.

Septic ulcer (pyrogenic ulcer)—The author considers that this term should be limited to ulcers due to the pyrogenic cocci usually the streptococcus and within the staphylococcus. The ulcer often begins as a small pustule or group of pustules, or as a bulla containing pus which soon bursts. Clinically the appearance is not characteristic and diagnosis is made on the finding of pyogenic cocci and absence of *C. d. pharyngae* and *Micrococcus (Coccobacillus) pyogenes*. Surely there are other organisms which should be taken into account. Treatment is by sulphonamides locally and orally and penicillin locally and by injection.

Tropicaloid ulcer (mycetoid desert sore)—An ulcer commencing usually as a vesicle which rapidly enlarges and bursts the condition is common in many parts of Africa and is often confused with true tropical ulcer or velvety sore. The pathology and bacteriology are very fully described and for full details the reader must be referred to the original paper. A Gram-negative coccus or cocco-bacillus (named by the author *Micrococcus (Coccobacillus) mycetoides*) is constantly found in initial lesions the organism growing well on 1 per cent tryptic agar and especially on 2 per cent glucose agar. It can be subcultured and the condition reproduced in human beings by application of cultures to scratched or abraded areas (performed in 13 cases) the ulcer is auto-inoculable and hetero-inoculable. Attempts to reproduce the conditions with organisms of the a isolated flora have failed and natural immunity does not appear to exist.

In a typical established case one to four ulcers are seen these may be open or covered with crusts and are usually on the lower two-thirds of the leg. The ulcers are round or oval, rather superficial rarely more than 4 cm. in diameter the margins being usually not undermined. The ulcers are seldom painful, the inguinal glands are not enlarged, and lymphangitis is never noted the lesions may occur anywhere on the body.

Clinically superficial, infiltrated or nodular, eczematoid crusty and general pyodermatid types are described. The ulcer has a protracted course of 3 to 12 months or longer.

In treatment, sulphonamides and penicillin should be tried, but the latter is too expensive to use in thousands of cases in some parts of the tropics. The patient is kept at rest for a few days and hot boracic fomentations are applied twice daily an ointment of 4 gm. dermatol (not described) and 25 gm. vaseline is then applied daily on a piece of gauze which is lightly bandaged on. Immediately before application it is useful to wash the sore lightly with hydrogen peroxide. The lotion described above applied once daily is often useful. Vaccines of the causal organisms seem to be useful for treatment in some cases.

The slightest abrasion should be immediately painted with tincture of iodine and long trousers worn instead of shorts if there is much chance of abrasion from shrubs etc. Vaccines give no protection.

[The terminology of ulcers found in the tropics has become rather confused and misleading. No mention is made of cutaneous leishmaniasis in this paper.]

C. F. Slack

MISCELLANEOUS DISEASES

LEWIS, H B, FAJANS, Ruth S, ESTERER, Marie B, SHEN, Chao-wen & OLIPHANT, Margaret The Nutritive Value of some Legumes Lathyrism in the Rat The Sweet Pea (*Lathyrus odoratus*), *Lathyrus sativus*, *Lathyrus cicera* and some other Species of *Lathyrus* *J Nutrition* 1948, Nov 10, v 36, No 5, 537-59, 1 fig [27 refs]

The authors, using young whiterats, 50-80 gm in weight, as their experimental animals, have tested the nutritive values and the toxicities of the following 8 species of *Lathyrus* *L. odoratus*, *L. sativus*, *L. cicera*, *L. hirsutus*, *L. tingitanus*, *L. aphaca*, *L. sphaericus* and *L. sylvestris Wagneri*

Those rats which were fed with 50 per cent of the pea-meal of *L. odoratus*—the one most fully described—uniformly showed signs of lathyrism, incontinence, paralysis of the limbs and spinal curvature coming on after a fortnight on this diet With older rats, weighing up to 250 gm, the same clinical picture was produced but the curvature was less marked In the femur, changes similar to osteomalacia were produced and in the tibia osteoporosis from demineralization There was haemarthrosis of the knees, strongly reminiscent of Charcot's disease in man The toxicity was the same even when casein to 25 per cent was added, or in the presence of good animal protein This is of interest in disposing of the theory that tryptophane deficiency is an aetiological factor in lathyrism The addition of powdered liver extract to the diet also failed to protect against the onset of symptoms of lathyrism, nor did liberal amounts of ascorbic acid affect the issue

The toxic principle is thermostable, resisting 80°C for 24 hours, and 120° for 6 hours It can be removed by slow percolation of the meal with 30 per cent alcohol, or by cold water, but not by ether

Analogous details are given, but less fully, of the results of feeding the animals with the other 7 species of *Lathyrus* *L. sylvestris Wagneri* was the most toxic of all With this, some of the animals showed symptoms of poisoning after only 4 gm of the legume had been taken, the animals would refuse the food in 2-3 days and died between the 4th and 10th days The symptoms also were more severe there was excitability, convulsive seizures with increased and spasmodic respiration The attacks could be induced by slight stimulation such as knocking on the cage or touching with a rod Older rats showed a similar train of symptoms but in them the onset was, as a rule, later The effects in those which survive appear to be permanent and in one instance it is reported that these attacks could be induced some 8 months after the *Lathyrus* had been withdrawn

The authors summarize the results of their experiments with the young white rats in the following words —

Lathyrus sativus and *cicera* showed no toxicity and promoted growth as effectively as did the edible white split pea of commerce *Lathyrus aphaca* was nontoxic but was inferior in growth promotion to the other species

Lathyrus hirsutus, *tingitanus*, *sphaericus* and *sylvestris Wagneri* were toxic, and the last three were unacceptable to rats (they are listed in order of increasing toxicity) Of these, *Lathyrus sylvestris Wagneri* was most acutely toxic and appeared to contain a toxic substance which produced marked injury to the nervous system The toxic material of *L. tingitanus*, *sphaericus* and *sylvestris Wagneri* could be extracted by 30 per cent alcohol and the extracted meal was effective in promoting growth

With the species less acutely toxic (*L. hirsutus* and *tingitanus*) it was possible to obtain the skeletal changes described as typical of lathyrism "

BERT E. \ Pigmentation of the Tongue in African Children. *East African Med J* 1948 Nov v 23 No. 11 433-7

It is concluded that pigmentation of the tongue is not of any apparent clinical significance in Lala children.

"It is possible that the back end of this condition will be found to vary in different groups living under different environmental conditions."

SINHA, S. B. Two Cases of Tropical Eosinophilia in Tes Estate Practice. *Indian Med Gaz.* 1948 Sept v 83 No. 9 421.

VISWANATHAN R. Pulmonary Eosinophilosis. *Quart J Med (n.s.)* 1949 Oct., v 17 No. 68, 257-70 * figs. on pl. [43 refs.]

After reviewing the relevant literature the author discusses the aetiology and symptomatology of pulmonary eosinophilosis (or tropical eosinophilosis). The clinical material was provided by 707 patients of whom 189 were army personnel on active service in E. Bengal, Assam, and Burma. Predominant symptoms were cough, lassitude, breathlessness on exertion, fever, asthma, heaviness or pain in the chest, haemoptysis and palpitation. Splenic enlargement was found in 76 per cent. of cases.

Characteristic mottling of the lung fields was found on X-ray examination in 51 per cent. of cases; this was sometimes uniformly distributed throughout both lung fields, and sometimes confined to one lung or a part of a lung. The eosinophils were raised above 4,500 per cmm. in 86 per cent. of cases and above 10,000 per cmm. in 49 per cent. of cases. There was a raised ESR in 73 per cent. of cases, a high titre cold agglutination in 78 per cent., a positive W.R. in 49 per cent., and a positive Paul Bunnell reaction in 73 per cent. of cases. Microscopical and cultural examinations of both sputum and blood in 17 cases failed to reveal any specific organism, nor were parasites found in specimens of sputum from 21 patients after examination by the method described by CARTER, WOOD and D'ABERRA (ibid. *Bulletin* 1945 v 20 73). Total and differential white counts made during the course of treatment showed an initial increase in the eosinophils and a subsequent fall. The reduction in the eosinophil count was not so rapid as the amelioration of symptoms and general counts were not obtained until a week to a month after the completion of treatment.

Exacerbation of symptoms and an increase in the eosinophil count after an injection of 0.15 gm. of neosarphenamine were used as diagnostic criteria to distinguish pulmonary eosinophilosis from other conditions causing eosinophilia, particularly asthma.

Routine treatment consisted of one injection of 0.15 gm. neosarphenamine followed by seven injections of 0.5 gm. at weekly intervals. One patient developed arsenical encephalopathy and died after the second injection of neosarphenamine. Autopsy revealed multiple dark reddish brown areas both on the surface and within the tissues of both lungs. These areas varied in size from 0.5 cm. to 2.5 cm. in diameter and were peribronchial in distribution. Microscopically they consisted of tubercle-like nodules with a group of pus cells in the centre surrounded by a layer of monocytes.

Pulmonary eosinophilosis was considered by the author to be a distinct clinical entity probably an infection caused by an unknown sensitive organism.

H. T. H. H. H.

BERRE, L. A propos d'un cas d'éléphantiasis nostras [A Case of "Elephantiasis Nostras."] *Rev Méd Nav (Métropole et Outre-Mer)* Paris 1948, v 3, No 3, 299-305

A young man, aged 20 years, a cultivator living in a small village in Basses-Pyrénées, who had never before left his native mountains, came to Bordeaux with a diagnosis of elephantiasis-like oedema of the lower limbs

Two years previously he had had a pleural effusion, a milky fluid was obtained each time this was aspirated. He also had a swelling of the abdomen. A provisional diagnosis of hydatid cyst had been made, but was later abandoned. Soon after this, swelling of the lower limbs developed. Next year the condition was unchanged, but he had a febrile attack associated with arthralgia during which the swelling declined temporarily.

When he was seen by the author, he had massive oedema of the lower limbs, swelling of the abdomen with a little ascites, and a pleural effusion at both bases. The skin of the lower limbs was hard, thickened and indurated, and the movements of the limbs were restricted. The blood count was within normal limits except that there was a constant eosinophilia which varied from 12 to 20 per cent. This last observation suggested a parasitic infection, but no ova, cysts, or parasites were found in his stools, and no microfilaria in the night or day blood on repeated examination. A biopsy of an axillary lymphatic gland showed nothing significant except dilatation of the lymphatic channels.

An attack of pneumonia caused a temporary improvement and thus suggested fever therapy, this was carried out with several substances but was without good effect.

The author had used this case as the basis for a discussion on the aetiology of elephantiasis. He discusses the rôle of bacteria, especially the streptococci which he considers the aetiological agent in both "true" elephantiasis and "elephantiasis nostras".

The two points of interest in the case were the fact that the large central lymphatics were first involved and later the skin lymphatics: thus he considers a reversal of the usual order. The second was the eosinophilia which is unusual in the absence of any parasitic infection.

MONTALVAN, C. J. A. Enfermedades del hombre transmitidas por insectos y otros artrópodos [Human Diseases transmitted by Insects and other Arthropods] *Rev Ecuatoriana de Hig y Med Trop* Guayaquil 1944, Dec, v 1, No 4, 388-409

PROTOZOOLOGY GENERAL

JACOBY, N. M. & SAGORIN, L. Human Toxoplasmosis in England. Report of a Case. *Lancet* 1948, Dec 11, 926-8, 2 figs [30 refs.]

This is the report of a case, showing symptoms of involvement of the nervous system which suggested a diagnosis of toxoplasmosis.

An infant of four months was admitted to hospital with a history of persistent crying, anorexia and enlargement of the head. The mother, father and three other children were alive and well. No domestic animals were kept but the house was said to be infested with rats. The diagnosis was based on the clinical and serological findings as noted below.

The child was well nourished, but hydrocephalic. No important abnormalities were noted in heart, lungs or abdomen. The eyes were proptosed and showed deviation to the left and nystagmus. The fundi showed extensive chorioretinitis and optic atrophy, and vision was probably negligible.

Radiograms of the skull revealed thinning of the calvarium and areas of calcification in the cerebrum. The cerebrospinal fluid obtained by ventricular tap showed no organisms and cultures were negative. Animal inoculation with gastric washing blood and cerebrospinal fluid caused no infection nor were any toxoplasma bodies found in any material examined.

Antibody neutralization tests were carried out on the infant and mother. The infant gave a dubious reaction but the serum of the mother neutralized 25 skin-reactive doses.

The disease had not progressed at the time of the report.

The case would appear to have satisfied most of the criteria for diagnosis of toxoplasmosis short of the demonstration of toxoplasma bodies but it has to be conceded that in very few cases have these been demonstrated during life.

FRANKEL, J. H. Dermal Hypersensitivity to *Toxoplasma* Antigens (*Toxoplasmosis*). *Proc Soc Exper Biol & Med* 1948 July-Aug. 76, No. 7 634-8

Past and possibly latent infection with *Toxoplasma* have previously been demonstrated both by *Toxoplasma*-neutralizing antibody and complement fixation tests. Both these methods have drawbacks. Thus the neutralizing antibodies are unstable unless stored in the frozen state, the reading of the test cannot be done under a week, and results are often equivocal. It is also necessary to maintain a strain of *Toxoplasma* for the tests. In the case of the complement fixation test, the complement-fixing antibodies are evanescent and would appear to indicate a recent infection only.

These facts rendered it desirable to prepare *Toxoplasma* antigens suitable for skin test which would eliminate these drawbacks. The first antigen prepared was from *Toxoplasma* grown in the developing chick by inoculation on to the chorioallantoic membrane of 7-9-day-old chick embryos. The culture was harvested after 4 or 5 days, the membranes ground up, diluted with normal saline solution and then frozen and thawed repeatedly. The suspension was centrifuged, the deposit discarded and the supernatant fluid after addition of a disinfectant was passed through a Seitz filter. Uninfected membranes similarly treated acted as control antigens.

This antigen was titrated on guinea-pigs carrying latent infections of *Toxoplasma*. It was found that 0.1 cc. of a 1 in 50 dilution would produce erythema and induration of 30 and 15 mm. in diameter respectively after 24 hours while in normal control animals erythema of few millimetres only in diameter was produced. The control antigen produced an erythema of less than 5 mm. in diameter in both normal and immune guinea-pigs.

In testing this antigen on man an induration of 15+ mm. at the site of the test dose was considered a positive test if the control antigen gave an induration of not more than 4 mm. The reaction took 24 to 48 hours to develop.

The chick embryo antigen was later replaced by hamster and mouse antigen. These were prepared from the sediment of peritoneal exudate of heavily infected animals which had been infected by the peritoneal route. This had the advantage over the chick embryo antigen of being much richer in *Toxoplasma* bodies in proportion to the cells of the host animal and so possessed greater potency. The heparinized exudate was centrifuged, the supernatant discarded and the deposit resuspended in 10 times its weight of normal saline solution. The suspension was exposed to ultra violet light to kill the *Toxoplasma* and accidental contaminants and was then frozen and thawed repeatedly to break up the organisms. A 1 in 1000 dilution in 0.3 per cent. phenol-saline solvent was now prepared as the final antigen for use.

For the control antigen ground-up mouse or hamster spleen, treated in a similar manner was used

The antigens were tested for non-toxicity and sterility and then potency tests were carried out on guineapigs with latent *Toxoplasma* infections

In applying the test to human beings, the result was considered positive if there was induration of 10-30 mm and erythema of 10-50 mm in diameter after 48 hours. The control should not show more than about 3 mm diameter of erythema after 48 hours. The antigens prepared by the means described are referred to as *toxoplasmins*

When skin sensitivity to toxoplasmin is compared with evidence of neutralizing antibodies in patients, there is shown to be a high correlation. In cases where the skin test was positive and the antibody neutralizing test negative there was sometimes produced subsequently an anamnestic rise in the neutralizing antibody titre

The simplicity of the toxoplasmin skin test and the early reading of results are said to make this the most useful single aid in the diagnosis of toxoplasmosis, past or latent, where isolation of the organism is not possible

RUCHMAN, I & JOHNSMANN, R J Biological Properties of a Strain of *Toxoplasma* recovered from a Fatal Case of Congenital Toxoplasmosis
Imer J Trop Med 1948, Sept, v 28, No 5, 687-95, 4 figs [14 refs]

A fatal case of toxoplasmosis in an infant is described, from which the causative organism was recovered. [The statement in the first paragraph that where organisms cannot be demonstrated "the final proof must rest on the demonstration of cross-immunity with a known strain of toxoplasma" surely needs some modification as in all parasitic diseases the final proof is demonstration of the causative organism.]

Toxoplasma bodies were seen in brain material and inoculation into laboratory animals was successful. Cross-immunity studies were made between the strain isolated (C G) and a highly pathogenic strain (R H) from another source. These showed a high degree of cross-immunity between these strains.

The results give further corroboration to the prevalent opinion that probably there is only one strain of *Toxoplasma* involved in the human and animal infections which have been observed.

This case is a proved addition to the small number of cases where, in the human disease *Toxoplasma* has actually been demonstrated in the tissues.

ENTOMOLOGY AND INSECTICIDES GENERAL

WHEELSWORTH, A B The Insect Cuticle *Biol Reviews* 1948 Oct, v 23 No 4 408-51 7 pages of refs

WALTON, G A A Minute Bethyloid Wasp of Medical Interest *Proc Roy Ent Soc London Ser A Gen Entom* 1948, Dec 28, v 23 Pts 10/12 98

In Sierra Leone, West Africa there is a minute Bethyloid wasp *Scleroterma kollasteri* which frequently stings man especially if it is caught between the skin and the clothing. The Bethyloids are a family of Vespoïd Hymenoptera. *Scleroterma* is parasitic on the larvae of beetles, the eggs being laid on the surface of the host. We do not know of any previous record of Bethyloids stinging man.

- DETHIER V. G. & CHADWICK, L. E. Rejection Thresholds of the Blowfly for a Series of Aliphatic Alcohols. Reprinted from *J. General Physiol.* 1947 Jan. 20 v. 10 No. 3 47-53 [41 refs.]
- CHADWICK, L. E. & DETHIER V. G. The Relationship between Chemical Structure and the Response of Blowflies to Tarsal Stimulation by Aliphatic Acids. *Ibid.* 45-62 [17 refs.]

Using blowfly adults, *Phormia regina* from which the antennae and labella have been removed so as to eliminate the olfactory receptors the authors test the stimulative power of certain organic compounds when brought into contact with the taste receptors of the tarsal. The flies which are suspended by their wings from a waxed rod, respond to tarsal contact with a 0.1 M sugar solution by extending the proboscis, but this response can be prevented by the addition of an organic substance to the sugar solution. That concentration of a graded series of dilutions of the added substance which prevents the proboscis reaction is taken as a measure of the substance's stimulative efficiency and is referred to as its threshold of rejection. The technique has enabled series of related organic compounds to be tested and their stimulatory efficiency to be compared with their chemical structure and properties.

In the first paper the authors report studies on fifteen aliphatic alcohols and, in the second paper on eighteen aliphatic acids and one mineral acid. It is concluded that stimulation by the alcohols and the acids involves surface energy relationships but it is not certain whether their penetration into the receptor cells or accumulation in the cell membranes causes the excitation. The hydrogen ion is the most stimulative component of the acid compounds and it is concluded that the anion, rather than the undissociated acid, is next in importance. Substitutions and other structural alterations to the acid molecule lessened the stimulative power of the anion but this was counteracted usually by increased dissociation of the acid resulting in increased stimulatory efficiency due to the hydrogen ions.

The technique is recommended as having applications in the development of improved insect repellents and, possibly, for work on insecticides.

- HAYES J. L. Ecological and Biological Observations on some Coprophagous Sepidae (Diptera). *Proc. Roy. Entom. Soc. London* Ser. A, Gen. Entom. 1948, Dec. 28 v. 23 Pt. 10/12 99-101 1 fig. [14 refs.]

The Sepidae are a family of minute flies many of which breed in dung. Their biology has been somewhat neglected, perhaps because they have no direct medical importance.

The author records ten species of Sepidae in Egypt and describes details of the life history. The early stages are preyed upon and greatly reduced in numbers by certain beetles of the families Histeridae and Staphylinidae.

- LEWIS D. J. The Simuliidae of the Anglo-Egyptian Sudan. *J. an. Roy. Entom. Soc. London* 1948 Dec. 15 v. 90 Pt. 14 4 3-93 4 figs. on 1 pl. & 11 maps. [37 refs.]

The author gives an interesting and valuable account of the distribution of the fifteen species of Simuliids known in the Anglo-Egyptian Sudan the text matter being illustrated by a number of maps which show at a glance the distribution of the separate species. The species recorded are *S. alpinus*, *S. alcocki* var. *newlandi*, *S. boeckii*, *S. cervicornis* var. *S. damocles* & *S. dracunculoides*.

S. griseicollis, *S. impukane*, *S. lepidum*, *S. mcmahoni*, *S. medusaeformis*, *S. nigritarsis*, *S. ruficornis*, *S. unicomitum* and a new species as yet undescribed. Specific descriptions are not included.

Simulids flourish in the western tributaries of the Upper White Nile, in the main Nile below Khartoum, and in the Upper Blue Nile and Upper Atbara River areas. The lower part of the Nile in the Sudan is heavily infested with *Simulids*. This and certain instances of discontinuous distribution of species in isolated hill regions are discussed in relation to the nature of the water courses which probably existed in the Sudan in ancient times.

Some early accounts, dating back to 1822, of travellers' experiences of flies, now known to have been probably *Simulium*, are quoted.

The paper is not only concerned with the distribution of the species, bionomical notes are contained under species and in sections dealing with the topography and species of particular areas.

The two species biting man in the Sudan are *S. damnosum* and *S. griseicollis*, the former is probably the vector of *Onchocerca volvulus* to man in the Sudan [this *Bulletin*, 1948, v 45, 531], onchocerciasis is considered to be responsible for blindness in the Bahr el Ghazal Province [this *Bulletin*, 1935, v 32, 650]. *S. griseicollis* is a serious biting pest in the northern Sudan.

S. damnosum occurs both in the northern and southern Sudan. It has a wider range of breeding places in the Sudan than in Central Africa, being found on mud in rather placid waters with a speed of 2 km/hour, as well as in rapids. Pupae have been collected from mud, rocks, cords of fish-traps, on sedge and other plants, they occurred even at depths of 60 cm. The habits of the adult are as in other countries, it prefers wooded country but has been found biting in barren rocky desert several kilometres from breeding places. The possibility is mentioned that onchocerciasis may spread to areas populated by *S. damnosum* but as yet free of the filarial parasite.

S. griseicollis is distributed mainly in the lower Nile from the Gezira Area southwards. A small outbreak of flies usually occurs about December but the main fly season is about March, there being probably a reduction of breeding in the intervening period owing to the low winter temperature. In summer, the hot dry climate probably kills off large numbers of adults. This species occurs in immense dense swarms consisting of probably many millions of flies and extending from the river over the desert on both sides. The flies do not engorge readily on man but they cause intense annoyance by walking on exposed parts of the body, particularly on the head, and probing the skin. Engorgement on man is slow, taking from 4 to 16 minutes. Birds, domestic poultry, cattle, horses and donkeys are attacked viciously, and there are reports of donkeys, caged birds and poultry dying of mass infestations of the fly. Biting rarely occurs indoors, and ceases after twilight. Both sexes, but particularly the males, are found probing date and mango flowers. They can be seen resting on vegetation during the day but disappear at night. The day-time clouds which are so characteristic of heavy densities of this species may contain both males and females.

Breeding takes place mainly in unbroken river water, the larvae and pupae being found not only on sedge, roots, sticks and stones but—and this is of particular importance—on moderately hard mud in water flowing as slowly as 0.8 km/hour. Dense clusters of pupae occur at depths of 75 cm and probably deeper. In the Dongola area, on the lower Nile, and severely infested by this species, the Nile is 600 to 1,300 metres wide and even at low water is a large river. Owing to erosion and deposition there is both a constant slow destruction and formation of islands. The banks are also subject to changes in form. There is, therefore, a continual change in the position of the many mud areas suitable for breeding *S. griseicollis*. Breeding in this mud is profuse and probably far

exceeds the amount of breeding which occurs on ridges and other substrata.

The author draws particular attention to the importance of the environment. It is considered that earlier records of *S. griseocollis* having flown long distances (including up to 250 miles) probably overlook the fact that the swarms were derived from mass breeding on mud in local and placid waters and not from distant rapids as was supposed. However record of flights to 80 km. from the Nile seem to be true and the fly is known to occur in the desert near Dongola in numbers sufficient to cause annoyance.

Domestic animals are sometimes provided with protective smoke cloths or dark shelters during the day or they feed only outdoors at night. Protective smokes and clothing are employed by the human population. Flies are avoided in the fly season or outdoor work is done during windy weather. In the fly is less active. The use of repellents is thought to be the most practical large-scale measure against *S. griseocollis*. Undiluted liquid dimethyl phthalate has given promising results for *S. griseocollis* and *S. damnosum* flies shelter for only an instant on the treated skin. In view of the dry air and cool temperatures of the fly season it is not thought that sweat is a serious disadvantage to the use of this repellent.

Human agency appears to play little part in the dispersal of *Simulium* spp. in the Sudan. Irrigation schemes have been responsible for the occurrence of *Simulid* breeding in some places.

This paper contains much detailed information and should be consulted in the original by those interested in the bionomics of *Simulium* species and the problems arising in their control.

D. S. BERTON

MACKERRAS M. Josephine & MACKERRAS I. M. Simuliidae (Diptera) from Queensland, Australia. *J. Sci. Res. Ser. B* 1948 May 1 (No. 21) 2-14 text figs. 4 figs. on 2 pls. 14 ref.]

The authors undertook a survey of the Simuliidae of south Queensland, Australia, during the period February to June 1947 with a view to establishing the identity of the pest species generally considered to be *Austrosimulium bancrofti* (Tayl.) concerning the morphology of which conflicting literature had appeared.

Prior to this survey three species had been reported from Queensland but the present paper increases the number to eight species and one subspecies, four of the species and the subspecies being new to science. Keys and figures are given for the identification of adult pupae cocoons and larvae and notes on the biology of the species are appended to the systematic descriptions.

A. bancrofti was found to comprise two species which had hitherto been confused, namely *A. bancrofti* (Tayl.) and *A. pusillum* n. sp. the latter being the important biting pest of the inland region of Queensland. *A. bancrofti* (Tayl.) has nine antennal segments and *A. pusillum* ten; there are other minor differences. The immature stages are more readily distinguished.

The pest species *A. pusillum* has a very short season, apparently about March-April chiefly, the fly was beginning ten days after the flood waters come down and lasting for 10-14 days. Only in the event of repeated floods do further fly waves occur. The larvae and cocoon are found in the torrential (speed over 4 ft per second) turbulent muddy water and are attached particularly to the submerged branches and fronds of the tea tree *Melaleuca argentea*. As the flood waters recede larvae and living pupae are no longer found, but the intensive breeding during the height of the flood is apparent by the exposed masses of empty pupal shells in their cocoons. Adult *A. pusillum* occur in great numbers on the *Melaleuca* shrubs of the stream bed and the river

banks, they attack man and domestic stock viciously. They have been reported as following stock for ten to twelve miles from the breeding place but, otherwise, do not seem to disperse far from the water-courses.

Larvae of *A. bancrofti*, and of other species, entirely replace *A. pestilens* as the rivers slow down and become less muddy, but despite the large numbers of adults of *A. bancrofti*, and of other species, which must emerge, few or none have been found in the vicinity of the breeding places. Either their habits were cryptic or dispersal was rapid and wide. *A. bancrofti*, although known to bite man and animals, was not troublesome in Queensland.

S. ornatus Skuse was the only species seen to oviposit and the only species of which the eggs were found. The females did not enter the water but deposited their eggs at the very edge of the water on logs, grass, and rocks. Development from oviposition to adult probably required two to three weeks, the egg and the pupal stage lasting about five and three days respectively.

The subsidence of the floods followed by complete drying up of streams prompts the authors to suggest that there must be a stage, probably the egg, which resists desiccation and enables the inland species, including *A. pestilens*, to pass through the long periods of summer drought to which they are exposed.

In a brief discussion of the control of *A. pestilens*, it is pointed out that the terrain is difficult to traverse by land during the floods, but that the addition of DDT, if necessary from aircraft, to the torrents or the use of DDT-dipped cattle as poison baits, are methods worth a trial. At present, smudge fires are used for the local protection of man and animals.

An apparatus for breeding out larvae and pupae collected in the field is described and figured.

VARGAS, L. & DÍAZ NÁJERA, A. Nota sobre la identificación de los simúlidos de México. El subgenero *Mallochianella* n. n. [A Note on the Identification of Simuliidae in Mexico]. *Rev. Inst. Salubridad y Enfermedades Trop. México* 1948, Mar., v. 9, No. 1, 65-74, 2 figs. on pl. [10 refs.]

The English summary appended to the paper is as follows:—

"The authors present a key for the identification of seven genera of Simuliidae giving a new definition of them. Within the genus *Gigantodax* they propose the new name *Mallochianella* for a subgenus with *Simulium* (*Mallochianella*) *sibirica* (Enderlein), 1930, as the subgenus type. According to the new definition of *Gigantodax* its distribution now includes an Australian species, formerly the genus was considered as neo-tropical. For the first time now appear keys for the identification of the adults of the Mexican blackflies."

HERTIG, M. A New Genus of Bloodsucking Psychodids from Peru (Diptera Psychodidae). Reprinted from *Ann. Entom. Soc. America* 1948 Mar., v. 41, No. 1, 8-16, 13 figs. (12 on 2 pls.)

Descriptions are given of the female and male of *Harleya phlebotomica* n. gen. and n. sp. These flies are similar to sandflies of the genus *Phlebotomus* but the new genus is created on account of differences mainly in size, the wing shape and posture, the cibarium of the female, and in the male genitalia.

During extensive collecting of *P. verrucarum*, *P. noguchi* and *P. perniciosus* in connexion with studies on Carrion's disease small numbers of female *H. phlebotomica* were taken occasionally in houses, caves, pigpens, and on stone walls. Only six males have been found. They were taken in the vicinity of a stone wall on top of which ran an irrigation channel, an environment where numerous females were collected. Females were captured containing blood [? origin], they fed on man in the laboratory and were twice seen to bite man.

in natura. They fly with the short, hopping flight of *Phlebotomus*. The majority of the specimens were taken at altitudes between 2,000 and 2,400 metres. This zone is covered by the distribution range of the three species of *Phlebotomus* and is the upper limit for verruga; there is no evidence of any part which *Phlebotomus* may play in transmitting the disease. VAN DER KUYT E. Mosquito Records of the Netherlands Windward Islands. *Amer J Trop Med* 1948 Sept. v 28 No. 5 747-9

The Netherlands Windward Islands in the Caribbean sea consist of St. Martin, Saba and St. Eustatius. The population (3 823 in 1946) is diminishing. The short note describes the climatic conditions and gives a list of seven species of mosquitoes collected during a two-week survey in the dry season in April 1947. The mosquitoes collected were *Aedes aegypti*, *Culex quinquefasciatus*, *C. fatigans* (both common), *Aedes bushii*, *Culex americanus*, *C. bahamensis*, *C. habilitator* and *Democerites cencer*. No anophelines were taken although special search was made. There is little evidence of mosquito-borne diseases in these islands at the present time. Cases of malaria mentioned in Government reports have always been confined to people who had visited other islands. Of four people found at Curacao infected with *Wuchereria bancrofti* two at least may have been infected in the Netherlands Windward Islands. Autochthonous cases of dengue have been found but the last two cases of yellow fever were reported on St. Martin in 1879. H. S. Loren

PARKER, A. H. Stimuli Involved in the Attraction of *Aedes aegypti* L., to Man. *Bull Entom. Res* 1948 Dec. v 39 Pt 3 387-87 1 fig

The author has studied the rôle of warmth, moisture and smell as stimuli attracting female *Aedes aegypti* to the host.

The apparatus used consisted of a glass tube 29 cm. long and 5 cm. in diameter. Each end was fitted with a metal cup 1 cm. deep inserted below innermost and with netting stretched across a wide hole cut in its base. The tube was mounted in a chamber lined with white paper and illuminated by a diffused overhead light. Holes in this chamber allowed for the introduction of mosquitoes and test objects as well as for observation. The experiments were made in a room at $28 \pm 1^\circ\text{C}$. and 50-70 per cent relative humidity. It was not practicable to obtain mosquitoes of the same age for each experiment, but the tabular matter records the range of age for each group. They were fed solely on sugar solution.

For each experiment 30 mosquitoes were lightly anaesthetized with ether and transferred to the tube. When they had recovered counts were made at each half-minute interval during a five-minute period of the number of mosquitoes on the netting at one end. A test object (e.g. the hand) was then placed on the cup of this same end and counts were made a before. The

mosquitoes could not touch the test object. The first count was the "control" and the second the "test" count. This procedure was repeated at least twice for each object.

The author expresses the result as an Index of Attraction (I_a), derived thus —

$$I_a = \frac{100 T}{T + C}$$
 where T is the total number of mosquitoes observed on the netting in the presence of a test object, and C is the number observed in the absence of any test object.

An I_a of 100 indicates maximum positive response [attraction], of 50 indifference, and of 0 a maximum negative response [repellence].

Responses were determined for the hand, warmth (water in a flask at the temperature of the palm of the hand and at the palm temperature plus 1 to 4°C), cold moisture (water-soaked filter paper at room temperature), warmth plus moisture (water-soaked filter paper over the water flask at palm temperature), and cold sweat, representing smell (sweat-soaked filter paper at room temperature).

Warmth alone was found in ten tests to have no marked attractive, nor repulsive, effect ($I_a = 36.1$ to 56.9). The author considers the possibility that activation of the mosquitoes by warmth might have caused them to land on and leave the netting in rapid frequency with the result that the counts made at particular instants would underestimate the actual number of mosquitoes attracted to the netting by the warmth. However, the number of mosquitoes landing on the netting over a period of time in the absence, and in the presence, of warmth was 66 and 69 respectively, and it is concluded that warmth had neither a marked attractive nor activating effect.

The following mean I_a values were obtained from twelve tests of the other test objects: hand (69.6), warmth plus moisture (65.5), cold sweat (73.3), cold moisture (69.1). These results indicated attraction by all four objects but the activating effects induced by them required consideration. In this series, activation was estimated by (a) counting the number of mosquitoes leaving the netting in a given period of time and (b) recording the percentage probing at the netting. The numbers leaving the netting were 503 (hand), 576 (warmth plus moisture), 209 (cold sweat), 173 (cold moisture) 13 (no test object), while the percentages probing were 52.9 (hand), 59.3 (warmth plus moisture), 20.3 (cold sweat), and 21.9 (cold moisture). It is concluded that the Indices of Attraction for these test objects are misleading and that, if allowance is made for the activating effect of each stimulus, then the hand and warmth plus moisture are markedly and possibly equally, attractive and activating but that cold sweat and cold moisture are less stimulating in both respects. Of these, cold sweat appeared to be more attractive than cold moisture. This is presumed to be due to an olfactory stimulus inherent in the sweat. Statistical tests are applied in comparing data not obviously significant at inspection.

In further discussion of the lack of activation and attraction by warmth alone as opposed to the marked activation and attraction of warmth plus moisture it is postulated that response to warmth may take place only under certain conditions of humidity.

The work of DeLong *et al* (*Rep Nat Res Coun Insect Contr Comm*, Washington, 1945 No 176) is noted as being in general agreement with the results obtained in the present experiments but it is observed that CHRISTOPHERS (this *Bulletin* 1948 v 45, 40) records *Aedes aegypti* being attracted to warmth (40°C) and showing little additional attraction to warmth plus moisture and that moisture at room temperature had 'no attractive effect'. It is suggested by the author that whereas DeLong's experiments

were made in environmental conditions similar to those of the present study. Christophers worked at 25°C. and 83 per cent. relative humidity. His mosquitoes maintained solely on water. These differences, it is suggested, particularly in temperature and humidity, might cause the differences in response to warmth and to moisture which are apparent in comparing the results of Christophers with those in the present paper. HOLSTEIN M. Les sérums précipitants. Fabrication et limitation de leur temps de leur emploi pour la détermination du sang ingéré par les insectes hématophages. [Preparation and Reduction in the Time of using Precipitation Sera for detecting Ingested Blood in Insects.] *Acta Tropica* Basle 1948 v. 5 No. 4 209-28. [74 refs.]

The paper gives a good deal of attention to the history of the development of the precipitin reaction and describes several methods of making specific sera. The author has applied them to the study of blood in lice and bed bugs.

He used several methods for preparing specific sera and appears to have developed a novelty in one respect. Two hours before each inoculation of antigen the rabbit is given an injection of 10 cc. of 10 per cent. glucose in water. It seems that after this procedure the rabbit may be brought into use nine days after the commencement of its course of three injections.

On testing his sera on the remains of blood in lice and bugs which had been fed on man a positive reaction was obtained in *Proclitus* even up to the tenth day after feeding. [This appears to imply that the insects could survive for twelve days without further meals which is indeed remarkable.] In *Cimex* a positive reaction was obtained as late as 30 days after feeding. When louse were tested a few days after feeding positive were obtained even with blood diluted to 1 in 15 000. With both insects the reactions were shown to be specific to human blood for negative reactions were obtained with anti-louse anti-cow and other sera. P. J. Rodin

ROMAN E. & VALIN P. Invasion d'*Ornithodoros* dans une habitation humaine en Haute-Provence. [Invasion by Ticks of a Dwelling-House in Haute-Provence.] *Ann. Parasit. Humaine et Comparée* 1949, 27 No. 34 214-19. 2 figs. 17 refs.

The inhabitants of a farm near Forcalquier (Provence) had occasion to live a move installed in an upper bedroom which was situated just below a pigeon-hoist. This necessitated operations on the ceiling so that there was a communication between the room and the pigeon-hoist. In the floor of the stove, specimens of *Ornithodoros caniseps* (Can.) were found. This tick is uncommon and is a parasite of pigeons.

A number of persons in the house were bitten at night and the bites resulted in very intense pruritus with extensive oedema.

This is the first time that *O. caniseps* has been recorded in Provence.

TRAPIDO, H The Development of a Sprayer for Use with Water-Suspensions of DDT in Rural Areas of Latin America *Amer J Trop Med* 1948, Sept, v 28, No 5, 721-39, 16 figs on 5 pls

Sprayers originally designed for use with insecticide emulsions and solutions have been found unsuitable for use with water suspensions of DDT, because, among other things, of the sticking of valves and the plugging of nozzles. In practice, time is wasted in putting these right and the cleaning of nozzles and filters with pins and bits of wire results in damage to these parts and the delivery of erratic sprays. Power-driven sprayers are often impracticable and expensive to operate. Experienced mechanics are not always available to repair the machines and hand labour is often cheaper than motor-operated mechanical equipment. Moreover, some houses cannot be reached with truck-mounted power sprayers. What is required is a durable, simple, one-man, hand-operated, knapsack sprayer, capable of efficiently delivering DDT water suspensions.

This paper gives a full description of the basic unit and of the modifications made to it which overcome these disadvantages. The main alterations are the provision of a basket-type filter which is easily accessible and replaceable by hand, without the use of tools, a filler cap by-pass which may be rotated to open or close the sprayer, independent of the hose, by-pass or outlet pipe, a pressure release valve of the automobile type which can be used for releasing air pressure when the liquid has been expended and before the filter cap is opened, and by means of which air pressure can be put into the sprayer from a compressor whenever one is available, a second relief valve which is operated by finger pressure and a combined standpipe, funnel and preliminary filter, which is removable and permits filling of the sprayer to a standard level only, avoids wastage of DDT mixture when filling and screens the material as it enters the tank.

As well as describing the modifications the author illustrates his paper with scale drawings of the parts and photographs. *H S Leeson*

PARR, H C M & BUSVINE, J R A Spinning-Disk Sprayer for applying Residual Insecticides *Ann Applied Biol* 1948, Sept, v 35, No 3, 359-68, 5 figs

Ordinary knapsack sprayers have been found to be very satisfactory for applying residual insecticides to surfaces in dwellings, etc. When using a Kent type sprayer, the fluid is ejected in the form of a rotating hollow cone, which expands, and becomes thinner, forming threads and, finally, droplets. The origin of these droplets in a rotating cone gives them a variety of initial directions, the range of which is determined by their original velocity, depending on the pressure employed, and the size of the droplets. The larger droplets have more momentum relative to their air resistance (surface area) than the small droplets, consequently they tend to travel farther in still air. However, the movement of the cloud of spray droplets soon produces a forward air current which carries along the finer droplets. Therefore, very fine and coarse droplets travel farthest. Spray clouds from 1/16 in and 1/32 in nozzles, when water or kerosene were used at different pressures resulted in the production of droplets which varied considerably in diameter, but whose size mainly lay between 0.1 and 0.4 mm.

By using the spinning-disk apparatus described by the authors, droplets of the same order of size as those from a Kent type sprayer, i.e. 0.1-0.4 mm

diameter can be produced, and by altering the speed of rotation, many droplets of the required size between these limits, can be consistently produced. The apparatus can be used to coat various surfaces up to 1 ft. square or deposits of insecticides in oil solution or in aqueous suspensions or emulsions, and these deposits can be controlled and estimated with a fair degree of precision. As a result it is possible to apply a definite and known amount of insecticide to a surface and to repeat such deposits to within 3 per cent. error at the most.

The apparatus is fully described, and those interested should consult the original for details concerning the construction of the sprayer and the method to be employed when using it.

BONART R. M. A Comparison of DDT and Dichlorodiphenyl Dichloroethane as Larvicides for *Aedes* Mosquitoes. *J. Econom. Entom.* 1948 Oct v 41 No 5 834-5

"In laboratory tests with DDT and dichlorodiphenyl dichloroethane in xylene emulsions against *Aedes* larvae collected in salt marshes of central California, the latter compound was found to be two to three or more times as toxic depending upon the concentration used. Also *Aedes squamiger* was found to be much more resistant to both materials than was *A. dorsalis*. Both of these discoveries may have a practical application since (1) dichlorodiphenyl dichloroethane has been considered as a substitute for DDT where danger of residues to man, domesticated animals and wild life is a factor and (2) *A. squamiger* or *A. dorsalis* may frequently be found in pure culture, and can be treated with different dosages of larvicide when so found.

GISSELING J. M. Toxicity of Parathion to Mosquitoes. *J. Econom. Entom.* 1948, Aug v 41 No 4 649-50

Parathion, a new insecticide of German origin is an ester of thiophosphoric acid. It is highly insecticidal (but so dangerous to vertebrates that it is unlikely to come into general use).

The author has tested parathion against *Aedes aegypti*. Parathion as an emulsion diluted in water killed all larvae at a dose of 0.003 of a part per million. Used as a dust the same result was obtained with 1/300th lb. per acre. Quantities of DDT quoted for comparison are ten times greater for the same kill. Pupae are many times more resistant than larvae to both insecticides.

LABORATORY PROCEDURES

LEIBOVITZ, A The Thick Smear Identification of Malaria *Bull U S Army Med Dept* 1948, Dec, v 8, No 12, 956-8

A rapid method for staining thick drops of blood is described —

1 Apply eosin stain for 15 seconds The stain is prepared by adding eosin Y (2 gm) to a buffer solution of 17 gm of dihydrogen sodium phosphate, 5.6 gm of disodium hydrogen phosphate in 1,000 cc of water

2 Wash for 15 seconds in distilled water buffered at pH 7.2

3 Apply polychrome methylene blue for 60 seconds The stain is prepared by placing in a boiling water bath for 1 hour, 2 gm of certified methylene blue (not medicinal), 17 gm of disodium hydrogen phosphate in 100 cc of water Then 5.6 gm of sodium dihydrogen phosphate, 75 cc of methyl alcohol and 900 cc of water are added The mixture is ripened in the refrigerator for a week

4 Wash for 60 seconds in distilled water buffered at pH 6.0, and then for 5 seconds in water of pH 6.8

The advantage of this stain is stated to be that it brings out Schuffner's dots vividly throughout the thick drop It does not apparently stain Maurer's dots, so the method would be of little advantage in the numerous areas where the dominant parasites are *P falciparum* and *P malariae*

REPORTS, SURVEYS AND MISCELLANEOUS PAPERS

KYLE, J Health Regulations for Air Travel (II) *Brit Med J* 1948, Dec 25, 1115 [Summary appears also in *Bulletin of Hygiene*]

BARRETT [see *Bulletin of Hygiene*, 1948, v 23, 80] has recently discussed various aspects of health regulations for air travel including the international Convention for Aerial Navigation 1944, the vaccines which should be injected and their dosage and certain regulations affecting aircraft and crews He drew attention to the fact that practically all international flights are, from the point of view of quarantine, well within the incubation period of the major epidemic diseases

Kyle has continued these instructions and gives detailed information concerning the diseases against which immunization must be carried out for those travelling by British Overseas Airways (see table)

Doctors are advised to ensure that their patients are in possession of the international form of certificate recommended by the International Sanitary Convention for Aerial Navigation, 1933, as amended in 1944

"U.S.A. requires passengers from India, Pakistan and Syria to have cholera certificate.

"Japan requires children 1-15 years to be inoculated against diphtheria.

"Yes indicates that the inoculation or vaccination is an essential requirement without which the passenger will be held in quarantine on arrival or may not be permitted to embark.

"— indicates there is no requirement.

"R indicates that owing to the presence of the disease or other circumstances the inoculation or vaccination is desirable for the passenger but it is not an essential requirement.

"Protective inoculations against major epidemic diseases are required as follows: Smallpox for practically all routes. Yellow fever for journeys to

and from West and South Africa *Cholera* for all journeys to and from India and Far East It is also advisable to be protected if *en route* to West Africa and Egypt *Typhus* and *typhoid group* (T A B C) for these diseases protective inoculation is recommended, though not essential on all routes *Plague* for journeys from some airports in the Orient" F O MacCallum

CONGO BELGE Rapport sur l'Hygiène Publique au Congo Belge pendant l'année 1947 par le médecin en Chef de Colonie [Report on the Public Health in the Belgian Congo during 1947] 152 mimeographed pp, 1 folding map and 3 charts

This publication, like its predecessors [for 1946 Report see this *Bulletin*, 1948, v 45, 549] contains a wealth of carefully detailed statistical information and commentaries which one has come to expect in the reports of the *Médecin en Chef* of the Belgian Congo Figures are given for population, demographic distribution, incidence of diseases and deaths and the like over many years—in some cases for as far back as 1928

So complete and detailed a record does not lend itself readily to abstracting, but it may be stated that the seven chapters are presented on the usual lines, namely, (1) general organization and demography, (2) discussion of pestilential, epidemic, endemic and other diseases, (3) medical provision for the indigenous people, which includes that of the well-known Belgian organizations, FOREMI, FOMULAC, FSK, Congo Red Cross, missions, dispensaries and private practitioners, (4) medical teaching facilities provided by Government, missions and other organizations, (5) hospitals, dispensaries and laboratories, (6) port and urban hygiene, industrial hygiene and general sanitation and (7) statistical appendices

The following points are noted as of special interest in 1947 There were 34 cases of *plague* (6 bubonic, 24 pneumonic and 4 septicaemic), with 29 deaths, in the Lake Albert focus and 7 cases (3 bubonic and 4 pneumonic) with 6 deaths in Lake Edward focus Vigorous measures against rats were in operation and 197 896 persons received anti-plague vaccination There were no cases of *yellow fever* or *cholera* In addition to 2,281 cases of *smallpox* with 11 deaths among Africans, there were 4 cases of *variola minor* in Europeans (1 in Léopoldville Province and 3 in Equator Province) Over half a million vaccinations and nearly 2 million revaccinations were done during the year

There were 137 African and 49 European cases of *exanthematic typhus*, with no deaths recorded, 113 of the former and 27 of the latter occurred in Léopoldville Province, where the disease appears to prevail In Katanga, 4 European and 11 African cases of *murine typhus* were reported

There were 3 European cases of *cerebrospinal meningitis* (1 each in the provinces of Léopoldville, Kasai and Katanga) and 248 cases with 121 deaths in Africans Vaccination against the disease was done on a large scale

Twenty-six cases of *trachoma* were seen in Africans in Katanga, where alone the disease seems to be endemic

There were 4 035 European cases of *malaria*, with 14 deaths (0 34 per cent), one-third of them occurring in Katanga Province Thirty-two cases of *blackwater fever* with 9 deaths are reported in Europeans and 27 with 3 deaths in Africans, again Katanga was the area principally concerned Ten cases of *sleeping sickness* occurred in Europeans, with no deaths, 9,289 new cases were recorded in Africans

It is noted that 3 Europeans suffered from *yaws*, and one acquired *leprosy*.

There were 467 Europeans affected with *amoebic dysentery*, with one death and 13,012 Africans with 128 deaths The satisfactory decrease in mortality (0 98 per cent compared with 1 59 per cent in 1946 and 3 51 per cent in 1942)

is attributed to increased use of effective therapy. The problem is being attacked vigorously as far as helminthic infections and it is pointed out that in urban and rural areas alike, the campaign against insect-borne diseases must take account of these conditions.

There were 33 cases of rectal and 32 of vesical schistosomiasis in Europeans; the figures for Africans were 7,539 and 1,174. Filariasis (no further details given) occurred in 433 Europeans and 8,397 Africans.

Six cases of rabies were reported in Africans (5 each in the province of Kasai Katanga and the Eastern Province). There was one case in a European in Kasai (It is stated that this case was *in situ de guérison* and that of 6 African cases only 5 died; this as worded, would imply two recoveries in rabies). It is presumed that these cases were of suspected rabies.

The chapters in the Report which deal with the various medical services are full and informative. It is noted that 67,748 laboratory examinations were made and that 45,408 of these were Wasmann tests.

General hygienic measures such as anti-mosquito measures and destruction of rats are dealt with statistically as are the services provided for workers in various industrial occupations and the conditions from which they suffer.

This report constitutes an excellent account of the medical services in the Belgian Congo during the year.

H. J. O'D. Burke-Gaffney

AFRIQUE OCCIDENTALE FRANÇAISE. Rapport sur le fonctionnement technique de l'Institut Pasteur de l'Afrique Occidentale Française en 1946 [DURIEUX C.] [Technical Report of the Pasteur Institute in French West Africa in 1946.] 102 pp. 1948. Dakar. Grande Imprimerie Africaine.

The activity of the different laboratories concerned in this Report followed in the lines of the previous year (this Bulletin 1947: 44, 1948). The total number of specimens examined amounted to 33,817 consisting of 1,711 bacteriological, cytological and parasitological, 13,169 serological, 443 pathological and 2,309 chemical investigations. About half of these were derived from medical organizations in Dakar and the remainder from the Services and other sources.

Altogether over 5 million doses (or cc.) of various biological products were prepared. There were over 4 million doses of yellow fever vaccine produced and over 7½ million people received the vaccine during the year bringing the total now vaccinated by the Pasteur Institute at Dakar up to over 17 million.

The author notes once more the difficulty of keeping white mice for protection tests, and measures are being investigated to improve the housing and feeding of these animals. Nevertheless 337 protection tests for yellow fever were carried out (307 human, 30 animal). Most of the sera came from the main inhabitants of two villages where vaccination against yellow fever had been done systematically four and seven years earlier. 4 specimens were from Europeans who had been vaccinated in various countries. Detailed tables show in the case of the two villages referred to above that between the fourth and seventh year after vaccination the number of strongly positive protection tests fell from 79 per cent. to 51 per cent. while the weakly positives rose from 4.6 to 30.6 per cent. during the same period. The negatives only increased by 4 per cent. The author believes that yellow fever vaccination should be repeated within four to five years if an adequately immune population is to be maintained, and statistical tables in the text support this view.

Positive protection tests were found in 5 of 30 monkeys (*Cynopithecus*) examined. All came from India in 4 cases. Two human sera were examined diagnostically. One in a child gave strong positive result; the other child had been vaccinated against yellow fever. The other in a European

adult who had been vaccinated 7 months before, gave a weak positive result, the patient died and histological lesions of yellow fever were found in tissue specimens. This anomalous case is discussed at length.

A whole chapter is devoted to the subject of rabies vaccine and vaccination. During the year 19,648 ampoules of 6 cc of antirabic vaccine for human treatment and 965 ampoules of 20 cc for veterinary use were prepared. Forty-six treatments were given at the Institute in 1946. The cases treated there and in other centres in 1945 are shown in statistical detail. There were no paralytic accidents and only one death, and this may have been from intercurrent infection.

The remainder of the Report gives detailed statistical accounts and observations on the general laboratory examinations and the diseases encountered. There are a number of short papers on researches undertaken, some of which have already been noted in this *Bulletin*.

The Report is well presented and gives a very informative account of the work of the Institute and its related services. *H J O'D Burke-Gaffney*

PRIDI [? PRIDIE] Report on the Health Services of Iraq with special reference to the Incidence and Control of Endemic Diseases. *J Roy Faculty of Med of Iraq* 1948, July-Oct, v 12, Nos 4/5, 135-42.

This report summarizes in general terms the epidemiological features of the communicable diseases which are of major public health importance in Iraq, it is devoid of statistics. The chief endemic diseases are malaria, tuberculosis, schistosomiasis, hookworm disease, relapsing fever, typhus, trachoma and dysentery.

Malaria—The newly-formed Malaria Institute had the benefit of the basic malaria surveys carried out by the British Army malaria units during the war years. Rural malaria in Kurdistan is conveyed by *Anopheles superpictus* and control measures include residual spraying and anti-larval work. In the areas of the Middle Euphrates drainage and canalization are important. In urban malaria, the "usual methods" are employed.

Tuberculosis—A tuberculosis expert is to be appointed to survey the position and advise the Government, meanwhile a tuberculosis hospital is being built north of Baghdad and will be used as a diagnostic as well as treatment centre.

Schistosomiasis—A very severe recurrent infection of man with *S haematobium* occurs in the Lower Euphrates area, increase in irrigation will make matters worse. Elsewhere in Iraq, distribution of schistosomiasis is patchy but the situation has merited the appointment of a specialist in schistosomiasis to survey the position and advise the Government, the provision of an anti-schistosomiasis institute is suggested where field measures and mass treatments would be organized.

Improvements in water supplies and sanitation are necessary for the reduction of the incidence of hookworm, typhoid and dysentery. Relapsing fever and typhus are prevalent and until the standard of living and personal cleanliness can be raised, anti-louse measures are applied. Trachoma and other infective eye diseases are best dealt with by fly destruction by residual insecticides and the early diagnosis and prompt treatment of cases.

The health and medical services have developed over 25 years to form a "well organised efficient machine" with adequate facilities for training health and medical staff and quite capable of dealing with existing endemic disease. The author recommends that a whole-time professor of public health be appointed at the medical school in Baghdad, and that a principal Matron is necessary for the supervision of the nursing staffs and for inspection particularly

of provincial hospital. He stresses the importance of the close personal contact between the Medical Headquarters in Baghdad and the medical services in the country to ensure as far as possible a well-trained, contented and efficient staff.

R. F. T. M.

SWALE, J. R. H. & MYBURGH, C. A. L. A Sample Survey of the African Population of Southern Rhodesia. *Population Studies* 1948 Dec 2, 1, 3 30-33

CLERC, M. L'évolution dans la protection sanitaire du pèlerinage de la Mecque (Evolution of Sanitary Control of the Mecca Pilgrimage.) (*Pub. Indust. et Sociale*, 1948 Nov-Dec 1, 23 No 6 1949)

Brief reference is made to the important rôle which the Mecca Pilgrimage once played in the dissemination of cholera and other pestilential diseases into the world and the measures imposed by successive International Sanitary Conventions to cope with the evil. The Convention was last revised in 1926. Noteworthy results were achieved. Mecca has been free from cholera for 15 years or so. In recent years the health authorities of the Government of the Hedjaz have made an important contribution to the protection of the health of pilgrims and to the improvement of the sanitary conditions of the city and its population.

The development of air communications has introduced new dangers. Yellow fever has now to be considered a potential danger. That disease is now known to be endemic in territories that extend right across the African continent.

The Epidemiology and Quarantine Committee of the World Health Organization has drafted new regulations for consideration at the next International Sanitary Conference. These proposals include the compulsory vaccination of prospective pilgrims against yellow fever as well as against cholera and smallpox if they come from countries in which yellow fever is endemic. Further studies are recommended concerning the choice of cholera antigens producing a high degree of immunity. Vaccination against typhus fever would not be insisted on, but pilgrims who come from countries in which that disease prevails should be debarked. The Government of Saudi Arabia would undertake to keep all interested Governments informed of epidemiological occurrences during the pilgrimage and during two months before and two months after the event. If the pilgrimage has passed without any outbreak of cholera, plague, yellow fever, smallpox or typhus, north-bound returning pilgrim ships will no longer be required to go to the El Tor quarantine station; they will merely be inspected at Suez.

[No 5

SUMMARY OF RECENT ABSTRACTS*

IV TRYPANOSOMIASIS

General Epidemiology

The report on the Inter-Colonial Conference on Trypanosomiasis (p 584), which was convened in Lourenço Marques in 1946, contains much information on the distribution of *Glossina* and the trypanosome diseases of man and animals, methods of control (such as game destruction in S Rhodesia and the use of DDT sprayed by airplane) and clinical subjects. It is not a collection of papers describing new work so much as a series of statements of the position existing at the time. In 1948 a conference on tsetse and trypanosomiasis was held at Brazzaville, and was attended by representatives of the different countries. GEAR (p 770) has written a short general account of this conference.

PINTO (p 1070) reports on a survey of Portuguese Guinea in which 12,443 persons were examined and 248 cases of trypanosomiasis were detected.

Aetiology

FAIRBAIRN (p 50) discusses the results of infecting rats with *T. rhodesiense* taken from man early in the disease, in relation to the types of trypanosomes (as regards length) and their electrical charge. He believes that trypanosomes whose length is above the mean are mature, that they alone can enter into syngamy and produce infection, and that both negatively and positively charged forms are necessary for infection, and he describes the experiments on which these opinions are based. In comment, BROOM makes certain criticisms of the work, and these should be sought in the original.

VANDERPLANK (p 413) infected wart-hogs and elands with *T. rhodesiense*, and showed that the trypanosomes remained in their blood for long periods.

SANDGROUND (p 585) has succeeded, by inoculation of nursing rats, in enhancing the virulence of a strain of *T. gambiense*, and in changing its susceptibility to drugs and its general behaviour so that it became indistinguishable from *T. brucei*. In this state the strain remained stable. He argues that similar changes may take place in nature, and he holds the view, which agrees with the opinion previously expressed by HOARE, that *T. gambiense* and *T. rhodesiense* are mutant strains of a single species which the laws of zoological nomenclature would by reason of priority recognize as *T. brucei*.

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1948 v 45. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

VAN HOOB *et al.* (p. 303) have studied *T. brucei* in the Belgian Congo where, in areas in which *G. palpalis* predominates, it has been found in dogs, peccary and goats. *T. brucei* is more abundant than *T. gambiense* in the blood of peccary and dogs probably serve as the best reservoir. In dogs it produces a characteristic keratitis, and the dog may therefore be useful in differentiating *T. brucei* from the human trypanosomes. All attempts except one to infect man with *T. brucei* failed. In this one there was transient appearance of the trypanosome in the blood, but they could not be found later. This seems to indicate that some susceptible persons may carry *T. brucei* in nature and that the trypanosome strains, perhaps modified to adapt to man, may be transmitted by tsetse to such people. In some such way perhaps, a mutant strain of *T. brucei* may be produced which could affect man.

SICK (p. 317) reports that two laboratory workers in Switzerland became infected with *T. gambiense* not apparently by accidental inoculation, but by contaminating their fingers with infected blood in the course of their experiments.

Transmission

HEGH (p. 973) has written a useful book on tsetse flies, with special reference to those of the Belgian Congo. VANK (p. 883) has published a booklet on tsetse which would be intelligible to Africans who have had only slight education.

JACKSON (p. 874) has carried a stage further his investigations on a tsetse fly population in East Africa and has noted short-term fluctuations in death rate and birth rates, which cannot be associated with climatic changes but appear to depend on factors in the fly population. Male *G. morsitans* are relatively inactive in the first two weeks of life and during this period their death rate may be low. This has led the author to a re-calculation of the whole male population.

VANDERPLANK (p. 51) shows that if both males and females of *G. swynnertonii* and *G. swynnertonii* are kept together random mating occurs between the species, and the females cross-fertilized produce either sterile eggs or pupae which develop into sterile hybrids. He thinks that this process probably occurs in nature where the two species overlap and that it may be the basis of one means of control. He (p. 244) has investigated the feeding habits of *G. swynnertonii* and *G. pallidipes* in relation to interval between feeds in different climatic conditions. Flies classed as very hungry carry reserves of food and water sufficient for two days or less, those classed as replete carried reserves for a week or more. The periods are shorter when humidity is low or evaporation high.

The same author (p. 413) has studied the incidence of trypanosomiasis in game in East Africa, and records the results of examining a large number of *G. swynnertonii* and *G. pallidipes* for animal trypanosomes.

CHORLEY (p. 771) has obtained evidence that *G. morsitans* and *G. palpalis* are guided by their sense of smell more than is generally supposed, and that the smell of animal dung attracts them.

HORNBY (p. 1068) has written an account of *G. brevipalpis* and the types of vegetation in which it is found in southern Mozambique and of a trypanosomiasis survey of cattle in the same area.

SCHEVETZ (p. 484) reports a survey of Lake Tumba, in the Belgian Congo in which he observed that *G. palpalis* was rare along the shores of the lake but very prevalent along the bank of the rivers that flow into it.

NASH (p. 689) thinks that most sleeping sickness contracted by *G. palpalis* and *G. ticknelli* in Nigeria is transmitted in the late dry season when the temperature is high and when the flies have become restricted to permanent water such as village water holes where contact with man is close. If this is so it may be possible to reduce the length and out-protecting character of river crossing to that required for the dry season only.

The parasite of tsetse pupae, *Syntomosphyrum glossinae*, has been found by NASH (p 245) in Nigeria

GEIGY (p 873) has described his technique for maintaining a culture of *G palpalis* in Europe

Control

BUXTON (p 983) has summed up the known means of controlling tsetse

At a conference held in Nairobi in 1947, under the auspices of the East Africa High Commission (p 982) a resolution was adopted that the method of controlling *G morsitans* by destruction of game should be tested in more varied conditions than exist in S Rhodesia, and in relation to other tsetse flies, but that since clearing of fly is of little value unless full use is made of the land, plans should be made for settlement. Uncontrolled slaughter is condemned. The conference recognized the possibility that bush clearing, or the use of insecticides, or other methods now being studied, may prove better than destruction of game.

VAUGHAN-JONES (p 879) gives a general account of the aims and functions of the Game and Tsetse Control Department of N Rhodesia. In relation to *G morsitans* the Department has used game exclusion or destruction methods and also selective clearing, and the results in general are encouraging.

DU TOIT (p 52) describes the use of DDT smoke, emitted from the exhausts of low-flying aircraft, in the destruction of tsetse flies in South Africa. In this form, DDT will penetrate dense bush. He reports favourably on the method.

SYMES *et al* (p 588) have attempted the control of *G palpalis* by spraying Gammexane or DDT on vegetation once or more than once. In each experiment there was a considerable reduction in fly density for some days, but the numbers of flies soon began to increase. There was much absorption of the insecticides by the vegetation. The authors conclude that the method is not satisfactory.

GLASGOW and DUFFY (p 245) succeeded in eradicating *G palpalis* completely from an isolated stretch of riverine bush in Kenya by hand-catching methods in which teams of boys, with hessian screens, were used. They make the point that hand-catching speedily reduces *G palpalis* to a low density, and would therefore be expected to check an epidemic.

McLEITCH (p 502) has given an account of the methods used to control sleeping sickness in Nigeria since 1925, when the hitherto quiescent disease began to spread extensively. He discusses the clinical types of *T gambiense* infection, noting that the death rate may be high even where the disease appears to be mild. Treatment, which he outlines, is the first step in control, and is carried out by travelling teams and at dispensaries. Control of *G palpalis* and *G tachinoides* by clearing of streams, and in the Anchau corridor, are also described in this paper.

Clinical Findings

HARDING and HUTCHINSON (p 410) describe the *T gambiense* sleeping sickness observed in Sierra Leone, where an unusual form occurs in one area. In this form the trypanosomes are much more commonly found in blood than in gland fluid (which is most unusual in *T gambiense* infections), and the disease is mild even in patients with increased cell count in the cerebrospinal fluid. Although up to one-third of the population had been infected, the population had not decreased. Elsewhere in Sierra Leone the disease is of more usual type.

Noting that most Africans have an erythrocyte sedimentation rate which is higher than the normal for Europeans, HOLLINS and LEWIS-FANNING (p 1070) report on the rate observed in trypanosomiasis of man in Nigeria. Increase in the sedimentation rate is a feature of the disease, and corresponds roughly

with its severity. In trypanosomiasis a low rate indicates early infection or infection of low virulence. The authors think that if in a mass survey patients are found with high rates but in whom trypanosomes cannot be found, they should be given a single injection of antitrypal or pentamidine. If the rate has fallen when they are re-examined a month later they should be regarded as having trypanosomiasis.

HILL (p. 874) gives his reasons for advocating the Skard and Cantaloube method of measuring protein in the cerebrospinal fluid, and makes the point that as different methods lead to very different results, the method used should always be stated. In comment LOURIE states that at the Brazzaville conference in 1948 it was ruled that the upper limits of cell count and total protein (Skard and Cantaloube) for the lymphatic-blood stage of trypanosomiasis should be 3 cells per mm. and 0.025 gm. protein per 100 cc.

LAUCEL and CECALDI (p. 503) have found infection in patients (in West Africa) who had been treated for infections 5-7 years previously. They discuss the question whether these represented reinfections or reactivations after long latent periods but without reaching definite conclusions.

Discussing the transitory neurological signs observed in sleeping sickness, GELFAND (p. 411) describes a case in which the symptoms suggested cryptococcal or tuberculous meningitis, but trypanosomes were present in the cerebrospinal fluid and treatment with trypanamide and pentamidine was successful in removing the cerebral symptoms.

Treatment and Drug Prophylaxis

SCHZ (p. 878) writes of some reactions experienced by a patient being treated with various drugs for sleeping sickness.

It has long been known that Suramin (Bayer 205) persists for considerable periods in the body and that there is no particular tissue which acts as a storage depot. SPURKS (p. 772) has investigated the subject and has confirmed its low and persisting plasma levels. Closely related compounds also persisted, but therapeutic activity was not correlated with persistence. The possible hydrolytic products of Suramin were rapidly eliminated, so that it seems to resist hydrolysis in the body. The paper should be read in the original.

As a result of staining experiments at different hydrogen ion concentrations, SCHTELER (p. 313) concludes that when trypanosomes become drug-resistant there is a significant shift in the iso-electric point of the proteins.

HARVEY (p. 690) discusses the sulphhydryl and disulphide group in relation to arsenic resistance of trypanosomes but without finding a definite relationship which would explain the phenomenon. WILLIAMSON and LOURIE (p. 413) have confirmed the finding of an Hoot that melarsen oxide (which contains a melamine group) is active against arsenic-resistant trypanosomes. They discuss the mechanism of arsenic resistance and the action of the melamine group in the combination of melarsen oxide (and other substances) with the trypanosomes, but their argument should be read in the original. TREVITT and PELLISSIER (p. 877) report the results on a French equivalent of melarsen oxide given by mouth in sleeping sickness at Brazzaville but the period of observation was short. In a second paper (p. 877) they also report favourably on melarsen administered by mouth. Details of dosage are given.

CECCALDI *et al.* (p. 771) have been disappointed with their results in treatment of *T. gambiense* infections with *p-aminophenyl* butyric acid.

VODENOT (p. 181) has analysed the results of treatment of sleeping sickness in French West Africa, with pentamidine and LOURIE has constructed from his text a table showing these results. In high dosage the drug is effective up to but no later than, the time when the infection begins to involve the central nervous system. The author recommends intramuscular doses of 3 mgm. per

kgm body weight, repeated daily or on alternate days for 5 doses, but he used bigger doses in some series. SALEUN and CHASSAIN (p 875) have used pentamidine in French Equatorial Africa, intravenously in hospital but intramuscularly in the field, where intravenous administration to ambulant patients is regarded as too risky. Intravenous doses of 2 mgm per kgm each day for 8-10 days were rather too toxic, but with intramuscular administration even 3 mgm per kgm was not toxic. Pentamidine can be used in pregnancy. The results promise to be good, though the time of observation is short, there was a favourable effect in 26 cases which had proved refractory to other drugs. TRINQUIER and ARNOULT (p 313) also write very favourably of the results obtained in French Equatorial Africa by the use of pentamidine in early *T. gambiense* infections. Cure may be effected within 10 days in early cases, but the drug is inadequate in late cases, though it may be useful in association with trypanarsamide.

HARDING and HUTCHINSON (p 410) write favourably of antrypol and (especially) pentamidine in prophylaxis, they think that general drug prophylaxis is more effective than treatment of cases in checking an epidemic. SALEUN and CHASSAIN (p 878) in French Equatorial Africa report good results after a single intramuscular injection of 4-5 mgm per kgm pentamidine in prevention of infection, for a period of 6 to 8 months.

LAUNOY (p 1071) gives figures displaying the curative and prophylactic effects of pentamidine given subcutaneously to rats, against several species of trypanosomes. Although LAUNOY and JEANPIERRE (p 879) show that pentamidine given by mouth has little prophylactic action in rats against subsequent injection of *T. equiperdum*, LAUNOY (p 1071) reports that an insoluble preparation of pentamidine, when given by mouth to rats, exerts a prophylactic action against subsequent intraperitoneal infection with *T. gambiense*.

VAN HOOFF *et al* (p 412) show that in *T. gambiense* infections in the Belgian Congo propamidine and pentamidine have similar protective and curative properties, but that propamidine is more toxic, giving rise to paresis in some cases. Nervous symptoms could be avoided if propamidine was given intramuscularly. EERAEERTS (p 412) has used propamidine as a prophylactic in the Belgian Congo where he gave intramuscular doses up to 5 mgm [presumably of the isethionate] per kgm for adults. Two injections of the 4 per cent solution were given at an interval of 6 months, and very good prophylaxis was reported. In the dose of 5 mgm per kgm propamidine shows a strong tendency to produce abortion in pregnant women.

Animal Trypanosomiasis

HOARE (p 504) discusses the transmission of pathogenic trypanosomes of man and animals by biting flies other than *Glossina*, and shows that infection of domestic animals by *T. vivax* is a serious problem in some countries in which tsetse flies do not occur. He also discusses the possible relationship between *T. evansi* and *T. brucei* and thinks it possible that the former may have arisen from the latter or vice versa.

The chemotherapeutic activity of cinnoiline derivatives for *T. congolense* infections is discussed by KENEFORD *et al* (p 690). WILDE (p 414) has shown that cattle can be kept in excellent condition in East Africa, in spite of infection with trypanosomes (excluding *T. brucei*) by regular prophylactic treatment with a phenanthridinium compound or with Stibophen. He gives details of the different dosage schedules he used in this work.

CULWICK and FAIRBAIRN (p 313) have found *T. simiae* in two new hosts in East Africa—horse and cattle. They have measured these trypanosomes,

finding three forms which they discuss in relation to their theory of synergy in trypanosomes.

MARSHALL (p. 495) discusses the glucose metabolism of *T. cruzi* in relation to the trypanocidal action of certain drugs but the details should be sought in the original.

KLEINE (p. 689) discusses the control of surra in Russia and of animal trypanosomiasis in Africa.

BRESSANES *et al.* (p. 587) have succeeded in infecting a mouse by injection of a single *T. equiperdum* in one of 36 attempts. They failed with *T. gammas*. Failure to infect was quite common even when 50-100 trypanosomes were injected.

The distribution and rate of metabolism of phosphorus compounds in *T. equiperdum* have been studied by MORACZEWSKI and HILSET (p. 587) but for details the original abstract should be consulted.

HOPE and CHAPMAN (p. 505) give their reason for thinking that hypoglycaemia is the cause of death in albino rats infected with *T. equiperdum*. CHIX and MCCREARY (p. 505) have assayed on *T. equiperdum* the trypanocidal action of arsenical drugs by methods previously used for antimonials. Details should be sought in the original. CHIX and GRILING (p. 691) have been able to show that cysteine hydrochloride inhibits the effect of trivalent and pentavalent antimonials on the glucose metabolism of *T. equiperdum*. KOK (p. 691) has also shown that it inhibits the effect of nitrogen mustard on glucose metabolism. He (p. 773) has investigated the inhibition of certain glycolytic enzymes of *T. equiperdum* by antimonials and arsenicals.

DODD (p. 52) shows that the compound Furacin has a fairly high degree of activity *in vivo* against *T. equiperdum* and against various bacteria, when given as suspension by stomach tube. HARVEY and EVANS (p. 52) demonstrate that this drug has only a low degree of toxicity.

ERCOLE and WILSON (p. 773) show that BAL not only interferes with the toxicity of nitarsen but it also (and much more strongly) interferes with its therapeutic activity against *T. equiperdum*. A combination of the two substances therefore would not be suitable for treatment.

CALDWELL and GRÖGGS (p. 417) show that in rats maintained on a diet deficient in biotin, and infected with *T. lewisi* there was intense and prolonged infection. The effect of biotin deficiency is probably to cause diminution in the production of albumin and trypanolysin. TAYLOR and BECKER (p. 77) describe the liver changes observed in rat fed on a diet deficient in pantothenic acid and infected with *T. lewisi*. Such rats develop very heavy infections.

Chagas's Disease

DIAS (p. 1077) gives a general account of Chagas's disease in South America.

Chagas's disease has been found in many of the municipal district of Rio Grande do Sul, Brazil and carried by *Triatoma feda* (p. 11). TOFFI (p. 415) discusses the clinical features of the disease. It is seen in this area. HOWE (p. 415) found up to 23 per cent of people infected with *T. cruzi* in part of Bolivia where *T. feda* was the only known vector. Infection was also present in some dog and cat examined.

TOMIE and RYAN (p. 889) have grown *T. cruzi* in a dialysate medium. MATES and VARELA DE OLIVEIRA (p. 889) have cultivated *T. cruzi* in tissue culture and have observed that the entire cycle takes place in one cell. The paper should be read in the original. An autocatalytic medium, free from cell and coagulable protein, and in which *T. cruzi* can be cultivated, is described by DE FREITAS and DE CASTRO (p. 1073).

HACHENHA (p. 415) has compared the susceptibilities of male and (male) mice to various strains of *T. cruzi*.

MUNIZ *et al* (p 55) attempted to immunize monkeys with killed cultures of *T. cruzi*, but without success

MAZZOTTI (p 163) found natural infection with *T. cruzi* in *Triatoma protracta* *woodi* and *T. gerstaeckeri* in Mexico. A new species, *Triatoma delponte*, has been found infected with *T. cruzi* in nature, by ROMANA and ABALOS (p 314)

DE FREITAS (p 315) reviews the laboratory methods of diagnosis of Chagas's disease, which include xenodiagnosis, animal inoculation with blood from the patient, haemoculture, and the complement fixation test. He quotes a considerable amount of his own original work, and concludes that xenodiagnosis is the best diagnostic procedure, and that the complement fixation test is very useful, the other two procedures gave poor results. MUNIZ (p 54) describes a precipitin reaction which is particularly valuable in the early stage of Chagas's disease before definite symptoms appear. It is not very useful in chronic cases.

PELLEGRINO and MESQUITA (p 506) show that false positive reactions to the complement fixation test for *T. cruzi* infection may be given if sera are stored in the ice-chest before the test is performed, but that these false positive results can be avoided if the test is carried out on fresh specimens.

ROMANA and GI (p 316) refer to artificial xenodiagnosis, the patient's blood being drawn into a tube which is then covered with animal skin. The bugs bite through this skin and take in the blood. The test is useful if for any reason it is impossible to have the patient bitten directly by the bug.

DEANE (p 417) shows that Triatomid bugs are often found to be infected with *T. conorrhui*, which may lead to confusion in xenodiagnostic tests unless the flagellates are tested by injection into laboratory animals [which seems to be a most important fact].

MUNIZ and DE AZEVEDO (p 416) report experiments which indicate that there is an allergic condition in the pathogenesis of Chagas's disease.

POUDÉ *et al* (p 314) have performed the xenodiagnostic test and a complement fixation test on certain patients passing through the cardiology department of a hospital in Bahia, Brazil, the patients showed signs or symptoms which suggested Chagas's disease, and this was confirmed by one or the other of these tests. The symptoms of cardiac disease associated with Chagas's disease are described. POUDÉ (p 1074) found partial auriculo-ventricular block in 6 of 40 patients with Chagas's disease, and total block in 11. He describes other changes detected by electrocardiography in this series of cases. LARANJA *et al* (p 589) describe the electrocardiographic changes in Chagas's disease, and give details of the variations from normal which they observed. VALLS (p 416) made an electrocardiographic study of a considerable number of patients proved to have Chagas's disease having first excluded those with cardiac conditions due to other causes. Apart from a few cases of A-V block, the lesions found were slight and there was little impairment. Most of the patients were young. ROMANA (p 316) reports cases of chronic myocarditis and of encephalopathy due to Chagas's disease.

In Venezuela, PIFANO *et al* (p 1072) have cultivated *T. rangeli* from the blood of a girl suspected of Chagas's disease, and describe its characters.

MALARIA

PAMPANA, E. *Malaria in Europe 1938-1947. Epidemiological & Vital Statistics Rep WHO* 1948, Nov, v 1, No 18, 392-400 [Refs in footnotes]
[In parallel French & English]

[This is an interesting summary of all available information regarding the incidence of malaria in all European countries except Russia during the decade

which included the war years. The information is inevitably very incomplete but sufficient to justify the conclusion that outbreaks of malaria attributable to war conditions were much less widespread and severe than those which followed the 1914-18 war. The end of World War II coincided with the introduction of DDT as a residual insecticide. It is justifiable to conclude that they contributed materially to a lower malaria incidence than could reasonably have been expected.

FISCHER, L. Einheimische Malaria und Anophelesmücken in der Nachkriegszeit (Indigenous Malaria and Anopheles in the Post-War Period.) *Dtsch. med. Woch.* 1948 Nov. 8 v. 73 Nos. 41/4, 815-18, 3 figs. [1 ref.]

The article reviews briefly the past and present incidence of indigenous benign tertian malaria in Germany. In considering, with special reference to south Germany, the possibility of continued outbreaks the author discusses climatic factors, the habits and distribution of the *mosquitoes* and *typical* races of *Anopheles maculipennis*, the influx of gametocyte carriers, and the living conditions of the people under normal circumstances and as a result of the recent war. More importance is attached to *mosquitoes* than to *typical* as a potential vector. It is considered that limited foci of malaria may continue to occur where, as a result of the war, there is sufficiently increased contact between man and mosquitoes, but that mosquito destruction and amelioration of conditions should soon eliminate such outbreaks.

HOFMANN, R. Ein Beitrag zur Geschichte, Klinik und Epidemiologie der Malaria in Oberschlesien. [Malaria in Upper Silesia.] *Offenb. Gesundheitsdienst* Leipzig 1943 Apr., v. 9 Nos. 7/8 A 137-43 7 figs. [10 refs.]

Malaria—or rather fever which almost certainly was malaria—has existed in this district since 1870 though cases then were very few. From 1890 onwards the numbers increased rapidly—due to a large increase of small unimportant foci. In 1913 there were 100 cases reported. In 1917 862 and during this period, 1913-17 there were 2,149 cases reported. In the Bielefeld district, the infection is almost exclusively benign tertian. In Pless, malignant tertian has been found in several places and a few quartan infections. Clinically the disease is usually mild, cachexia is rarely seen. The vector is *A. maculipennis* and nearly all *mosquitoes*. Of 21 foci mentioned in which the mosquitoes were captured in byres, cellars and dwellings, in two the species is not stated, in one *A. typicus* alone was caught, in one *typicus* and *mosquitoes*, in the other 17 *A. maculipennis* only.

KLOSE, F. & EISENTRAUT, M. Das Auftreten der Malaria in der Provinz Brandenburg im Jahre 1942. [Malaria in Brandenburg Province in 1942.] *Offenb. Gesundheitsdienst*, Leipzig 1943 Nov. v. 9 Nos. 21/22, 1325-9.

In 1942 malaria became prevalent among prisoners of war in Brandenburg Province. The prisoners treated numbered 5,565 of whom 2,213 were Yugoslav, 1,815 French, 1,300 Russians and 237 British. Plasmosquine 0.41 gm. thrice daily for three days after two days of atabrin [mepacrine] 0.1 gm. twice daily were the drugs used and the results are stated to have been very good. There were among the Yugoslavs there were 353 cases between May and December 1941 but only 5 in the whole of 1942. During this year (1942) there were almost only 103 cases—the 5 Yugoslavs just mentioned, 63 Russian, 34 British and 7 French.

Among German soldiers serving abroad, those in Russia suffered more 8.6 per cent. in the northern theatres of war, 14.3 in the middle, 24.4 in the

southern and 14.1 per cent in unspecified places at the front. Two-thirds were first attacks, one-third were relapses. It is said that only 82 cases altogether occurred among the non-military population: 10 Germans, 23 Russians, 17 Croats, 12 Jugoslavs, 8 Ukrainians, 4 Hungarians, 2 Bulgars and one each of Italian, Slovene, Dutch, Belgian, French and Spanish. A list is given of nearly a score of places in the Province where conditions favour the development of *Anopheles*.

REV SANIDADE HIG PUBLICA—1946, Sept & Nov, v 20, Nos 9 & 11, 917–69, 1114–77. Estadística de los Dispensarios Antipalúdicos dependientes de la Dirección General de Sanidad [Statistics of Antimalaria Dispensaries of the Central Health Administration]

These statistical tables concern cases of malaria, fresh infections, diagnosed in each of the antimalaria dispensaries in each of the Provinces of Spain during the years 1944–45 and 1945–46 (1st June to 31st May). Tables record the incidence in five age groups, the incidence of *P. vivax*, *P. falciparum* and *P. malariae* infections, and the monthly incidence of each species of infection. The total number of new infections recorded in Spain in 1944–45 was 163,994, in 1945–46, 89,847. Of the latter 84,838 were *P. vivax*, 4,894 *P. falciparum*, 60 *P. malariae* and 55 mixed infections.

JERACE, F. La malaria nell'Agro Romano nel quinquennio 1943–1947 [Malaria in the Agro Romano 1943–47]. *Riv di Malarologia* 1948, June, v 27, No 3, 103–10, 1 fig & 4 graphs. English summary (9 lines)

This is a description of the severe epidemic of malaria that afflicted the Agro Romano in 1944. The Agro Romano is the territory that is subject to the administration of the Rome Municipality. It extends to and includes 48 kilometres of the coast line of the Tyrrhenian Sea and has a population of some 250,000. Malaria is endemic everywhere west of Rome, more particularly near the coast, but energetic measures before the war had brought the disease under control. In only two of the years between 1933 and 1943 inclusive did the annual notification of malaria cases exceed 2,000. In 1944, 9,063 cases were recorded of which 7,986 were primary infections: the highest monthly incidence was in August, 2,433. War damage, the suspension of malaria control measures, the immigration of troops many of whom were infected with malaria, the introduction of new strains of parasites, the scarcity of antimalaria remedies, and forced movements of the population were all important factors in contributing to the severity of the outbreak. In 1945, the total number of cases recorded rose to 11,025, of these, however, only 2,965 were primary infections. Thereafter there was rapid improvement. In 1947, only 495 cases were notified. During the first five months of 1948, only 78 cases were found: all of these were relapses and 45 were imported cases. DDT, which was first used in 1944, has contributed much to the noteworthy success of the control campaign.

BALZAR, M. Il pericolo della malarioterapia praticata in zone con anofelismo [Danger of practising Malaria-Therapy in Anopheline-Infested Areas]. *Riv di Malarologia* 1948, Apr, v 27, No 2, 65–70. English summary (7 lines)

In the Provincial Mental Hospital at Vercelli, the treatment of neurosyphilitic patients with malaria therapy was started in 1938, at first by inoculation of infected blood and later by mosquito transmission. Nothing untoward happened till 1943 when 33 cases of locally acquired *P. vivax* infection occurred among

the inmates and staff of the institution and 7 cases among the nearby tribal huts of Verelli. In the two following years the numbers of primary infections were 53 and 8 and 131 and 12. The anopheline density in these years was probably much increased. The scarcity of food was such that rice cultivation was allowed close up to the inhabited parts of the town. The scarcity of materials and disorganization generally arising from the war prevented the application of prompt measures of control. In 1946 the hospital buildings were treated with DDT with excellent results. In that year only four fresh infections were acquired in the hospital and only 6 in the vicinity. The author concludes that malaria therapy should not be practised in areas in which vector mosquitoes are prevalent unless supplies of DDT are available for the adequate disinsection of at least the quarters in which the patients in question are housed.

Verma Mitr

SCHWITZ J. Notes on Endemic and Acute Malaria in Central African Kaffirs. *Trans Roy Soc. Trop Med & Hyg.* 1949 Jan. v 43 No. 4 403-8.

In endemic malaria areas in Central Africa, parasite rates are much higher among African children than among African adults. In children *P. falciparum* dominates but *P. malariae* and even *P. vivax* infections occur with gametocytism of all three species. In adults only trophozoites of *P. falciparum* are found with occasional rare crescents. In hyperendemic areas, the peak of infection is reached at the age of 1 to 2 in hypoendemic areas at from 5 to 8 years. In the latter the *P. malariae* infection rate is low and *P. vivax* is very rare.

In infants, congenital malaria has not been found. *P. falciparum* appears first, later *P. malariae* and last *P. vivax* infections.

In endemic areas the diagnosis of fever of malarial origin may be difficult; the parasites may only be commensals. The macroscopical blood picture can be a useful aid to differential diagnosis. In endemic malaria, large and somewhat thick trophozoites in cells with specific alteration (deeper coppery colour and Stephens-Maunder dot) are characteristic. In acute malaria more trophozoites are found which have not yet been able to cause alterations in the red cells.

In high plateaux of Central Africa, epidemic malaria sometimes occurs. In epidemic malaria adults and children are infected in like proportion and both groups may show parasites of *P. malariae* and even of *P. vivax*.

Hsu, Kuo-Chin. Malaria in Southern and Western Szechwan with a Note on the Occurrence of *Schistosomus japonicus*. *Chin Med J. English Ed.* 1948 June v 68 No. 6 319-23. 20 refs.

This is a record of a journey made in the south west part of Szechwan. In each of nine localities children under 12 years of age were examined. Blood smears from all children with splenic enlargement were examined. Enquiries were made from local medical practitioners regarding the incidence of malaria. Collections were made of anopheline larvae.

Malaria was very prevalent in Suifu where spleen index of 28.5 was recorded in 1939 it was only 6.1 per cent. The movements of troops and refugees contributed to the increased prevalence which was specially marked after the completion of the aerodrome. *P. falciparum* infections became much more numerous. Of 1189 positive blood smears 68.6 per cent contained *P. vivax*, 28.6 per cent *P. falciparum* and 2.8 per cent *P. malariae*.

A. hyemalis var. sinensis was the most prevalent anopheline. It was found breeding in rice-field, slowly moving streams, stagnant ponds and in a variety

of collections of casual water. Other species found, in small numbers, were *A. minimus*, *A. palloni*, *A. barbirostris* and *A. hyrcanus* var. *ingerrimus*.

The author found a boy suffering from *Schistosoma japonicum* infection. *Oncomelania* snails were found in many places. Ankylostomiasis was very prevalent.

MIYAO, I., TAKEI, H., HATORI, J. & NODA, H. Investigative Studies concerning Malarial Infection among the Natives of Kainanto. *Kitasato Arch. Exper. Med.* 1942, Aug., v. 19, No. 2, 73-84. [21 refs.]

HERNÁNDEZ LIRA, P. Algunos aspectos de la epidemiología del paludismo en el nordeste de la República Mexicana. [Epidemiological Aspects of Malaria in the North-Eastern Part of Mexico.] *Bol. Oficina Sanitaria Panamericana* 1948, Aug., v. 27, No. 8, 699-705. English summary.

This is a short description of a malaria control programme intended to cover an area of north-east Mexico, triangular in shape the points of which are the three towns Matamoros, Nuevo Laredo and Monterrey. Work has been started in Monterrey, an industrial city of 232,000 population. The Antimalaria Dispensary of Monterrey report that the average annual incidence of malaria cases during the last five years has been 550. The examination of 1,500 school children gave a spleen index of only 3 per cent. Malaria parasites, *P. vivax*, were found in only 1.9 per cent of 2,000 films examined.

The more important breeding places of anophelines in the city are listed. Four species of *Anopheles* have been identified: *A. pseudopunctipennis*, *A. punctipennis*, *A. quadrimaculatus*, and *A. albimanus*. *A. pseudopunctipennis* is the most prevalent especially during the months June and July, and from September to November inclusive. A private company has undertaken considerable engineering work designed to eliminate mosquito breeding, and DDT has been used extensively. When the work in Monterrey is completed Matamoros will receive similar attention.

DUBIN, I. N. A Search for Exoerythrocytic Forms in Human Malaria by means of Tissue Cultures of Bone Marrow. *J. National Malaria Soc.* 1948, Dec., v. 7, No. 4, 330-32.

"In a search for exoerythrocytic forms in human malaria, tissue cultures were made from the bone marrow of patients with sporozoite-induced infections, both in the pre-patent period as well as after development of parasitemia. This was done in *P. falciparum* infections in 6 instances and in *P. vivax* infections in 20 instances. No exoerythrocytic forms were seen in the cultures."

WACKERLAS, M. J. & ERCOLE, O. N. Observations on the Development of Human Malarial Parasites in the Mosquito. I. Morphological Changes. *Australian J. Exper. Biol. & Med. Sci.* 1948, Sept., v. 26, Pt. 5, 439-47, 2 figs. & 1 coloured pl. [17 refs.]

This is an account of the development of *Plasmodium vivax* and *Plasmodium falciparum* of Melanesian strains in *Anopheles punctulatus punctulatus*.

The preparations for study were made from mosquitoes fed on gametocyte carriers and dissected at varying intervals after the blood meal. The preparations so obtained were air-dried and stained by Leishman's stain.

Material at late stages in the infection was examined in fresh preparations or after fixation and staining by various standard methods.

The events in sporogony are described on familiar lines and speculation is made as to whether the two masses of chromatin often seen in the female

gametocytes indicate meiotic division preliminary to fertilization or when they are the male and female nuclei prior to fusion.

Development of the ookinete and the oöcytes on the outer surface of the gut wall is described, but no new facts are brought out. The growth of the oöcyte under similar conditions was said to be more rapid in the case of *P. vivax* than in that of *P. falciparum* sporozoites entering the glands two or three days earlier in the case of the former parasite.

Infected mosquitoes kept for any length of time showed a steady decline in sporozoite content even when they were fed on carbohydrate food only.

H. E. SHAW

MACKERRAS M. J. & ERCOLE Q. V. Observations on the Development of Human Malarial Parasites in the Mosquito. II. Factors Influencing Infection. *Australian J. Exper. Biol. & Med. Sci.* 1943, Sept. v 20 Pt. 3 413-54, 2 figs.

An attempt is made to assess the influence of various factors on the infections produced in anophelines fed on gametocyte carriers of *Plasmodium vivax* and *P. falciparum*.

The probable number of gametocytes ingested by the mosquito is first considered and then the findings in each of the two species are considered separately.

P. vivax.—The results obtained in infecting mosquitoes were often contradictory and no factor relative to either insect or plasmodium could be demonstrated as the cause of greater or lesser infection rates in the mosquito.

P. falciparum.—Here again equivocal results seem to have been obtained and the curious inference is drawn that immature gametocytes can produce oöcytes but that these do not develop normally as will be evident from the following quotation—"these gametocytes were of the usual crescentic shape, but many were apparently immature as large numbers of the cysts which formed died before reaching maturity and the sporozoite rate of the hatch was only 42 per cent."

The case of one patient is described where gametocytes of *P. falciparum* consistently failed to infect mosquitoes and this is put down to "some inherent functional peculiarity the cause of which is quite obscure. [There would appear to be at least the possibility that some other less obscure cause was operating, such as the surreptitious use of paludrine.]

The causes responsible for reduction of viable gametocytes in the first 24 hours after the mosquitoes' blood meal are considered, such as the well-known phenomenon of phagocytosis. The description given of one batch of mosquitoes which were fed on a *P. vivax* gametocyte carrier in which the mosquitoes showed numerous minute brown spots on the gut wall. These are interpreted as representing the points of penetration of the gut wall by vermiforms which later failed to form oöcytes. This seems improbable.

H. E. SHAW

SAUNDERS, G. M. TALMAGE D. W. & SCOTT V. The Use of *Plasmodium vivax* Preserved by Freezing in Inducing Malaria. *J. Lab. & Clin. Med.* 1943, Dec., v 33 No. 12, 1579-87.

The therapeutic use of malaria continues to be so widely practised that any easy method of maintaining a strain over long periods without the use of human subjects would be of great advantage.

It was for this reason that the method here described was worked out and tested. Blood from malarial donor was collected and prevented from clotting

either by mixing five volumes of blood with one volume of 4 per cent sodium citrate, or by defibrinization

The blood was next transferred to thin-walled glass ampoules in two to four ml amounts and these were sealed in a flame. The contents were next rapidly frozen by immersion of the ampoules in a freezing mixture of ethyl alcohol and dry ice at -70° to -80°C . By rotating the ampoules individually freezing was complete in a few seconds and the ampoules were then stored in dry ice at -70°C . For use, the ampoules were rapidly thawed at the bedside by immersion in a water bath at 40°C and the contents immediately inoculated intravenously, two or three ampoules being used for one inoculation.

Results—Successful transmission of malaria was obtained after more than five months storage of blood and the overall success rate in 46 subjects was 87 per cent [40 subjects]. The possible causes for the failures are discussed, such as previous malarial infection, race, inadvertent use of antimalarial drugs, the stage of the malarial parasites when frozen, and other factors.

There was no significant difference in the results obtained with defibrinated and citrated blood, nor did the length of storage appear to affect the results.

The average incubation period was 12.4 days, somewhat longer than after direct transfers of blood but the clinical course of the resulting malarial infection differs in no way. The preservation technique caused haemolysis of the red cells, thus freeing the parasites, which showed poor staining reactions but no untoward results attributable to the inoculations were seen in patients.

MACKERRAS, M. J. & ERCOLE, Q. N. Observations on the Life-Cycle of *Plasmodium malariae* Australian J. Exper. Biol. & Med. Sci. 1948, Nov., v 26, Pt 6, 515-19, 3 figs.

Although quartan malaria is widely distributed throughout the tropics, much less is known about its life history than that of the other malaria parasites. Melanesian strains in particular have been little investigated and this paper remedies the defect to a small extent. A number of *Anopheles punctulatus punctulatus* were allowed to feed on a carrier of *P. malariae* gametocytes in New Guinea and were then sent to Cairns, Australia, where they were kept at 73°F . Oöcysts, 25μ in diameter, were present on the 16th day. These cysts showed the typical distribution of fine black pigment in double lines. A light infection of sporozoites reached the glands by the 31st day or slightly earlier. At this same temperature, *P. vivax* takes 15 to 16 days and *P. falciparum* 18 to 20 days.

Five mosquitoes of this batch were still alive on the 24th day and for the next 10 days they were given an opportunity to feed on a volunteer who actually received 11 bites during this time. Three of the five mosquitoes harboured sporozoites. Parasites were first seen in the man's blood 24 days after the first bite, symptoms of the disease started a fortnight later still. Two other volunteers received inoculations of blood containing the infection. All three cases were mild and the parasitaemia did not exceed 2,300 per cmm. Gametocytes were first seen 23 days after the appearance of trophozoites, they were never numerous and they proved uninfecive to mosquitoes.

The morphology of the parasites was studied in one of the two blood-infected volunteers who exhibited a typical quartan fever. By 24 hours the parasites contained pigment and were "amoeboid" in shape. By 48 hours the trophozoite almost filled the blood cell and division of the chromatin had started. By the 64th hour, division of the chromatin was completed and the pigment had aggregated. Merozoites numbered 5-10 the average being 8.

[It will be noted that this Melanesian strain shows few differences from the classical form.]

GAUD J Rythmes saisonniers d'activité d'*A. maculipennis* et d'*A. claviger* au Maroc en fonction de l'altitude. [Seasonal Breeding of *Anopheles maculipennis* in Morocco in relation to Altitude.] *Bull Soc Path Ex* 1948 v 41 Nos. 7/8 494-8 1 map & 1 graph.

The behaviour of *A. claviger* and *A. maculipennis* var *labr. achasi* was compared in the plains and mountains of Morocco. The latter species constitutes more than 80 per cent. of the total anopheline population and is the principal vector of malaria. Both species breed in slowly running water rich in vegetation in fact the same breeding places are used by the two mosquitoes. In the mountains *A. claviger* is first found alone then the two are found together during the hot season and later *A. maculipennis* disappears. Below 500 m. development of *A. maculipennis* continues throughout the year at 1,000 m. it is for only for six months and above 1,500 m. only for four months. The breeding of *A. claviger* is also influenced by altitude its upper limit is well above 2,000 m. and its lower limit in the summer months is about 1,000 m. The author suggests differential control by larvicidal measures as opposed to permanent work based on these observations. P C C Geraud

TAKI H Experimental Studies concerning the Growth of Anopheles in Sea Water in Katsuta. *A. Iwate Arch Exper Med* 1944, Aug v 10 No 2 103-8.

1 We observed the growth of anopheles larvae in sea water

2. Many species of anopheles are found in the southern district of Katsuta but only *A. agus* hatched.

ROBERTS J I A Parasitological Survey of African School Children in Nairobi Schools with Haematological Results of Malarial Infections. *J Trop Med & Hyg* 1949 Feb v 5 No 2, 31-3.

A survey was carried out on African school children living in Nairobi, Kenya who belonged to several tribes. The results are given in four tables. About a quarter of the children showed malaria parasites in their blood and three-quarter had intestinal helminths. The malaria was chiefly caused by *P. falciparum* though *P. m. lariae* (4 per cent) and *P. m. s.* (0-24 per cent) are occasionally seen. Helminths included species of *ascaris*, *Ascaris lumbricoides*, *Tenon* and *Sci. stenosoma* in that order of prevalence. *E. lamblia* & *stolytica* was found in 5 per cent of the children.

Fifty children suffering from malaria were investigated haematologically. The average red blood count was 2,650,000 per cmm. the haemoglobin 8.4 gm., and the total white cells were 19,000 per cmm. including 2 per cent pigmented forms. It is stated that the diet of these children was comparatively poor in the haemoglobin-producing element. P C C Geraud

ROBERTS J I A Comparison of Haematological Results in Europeans and Africans suffering from Active Malaria. *J Trop Med & Hyg* 1949 Nov v 51 No 11 228-34.

A study was made of the effect of malaria on the blood of patients during an epidemic of the disease in the town of Nairobi, Kenya Colony. 200 Africans and 100 Europeans were observed and an attempt was made to assess the degree of disability arising from the anaemia caused by the infections. The malaria was chiefly due to *P. falciparum* and medium or light infections were commonest (in four fifths of both the European and African groups). The author states however that the numerical prevalence of parasites is no guide to the severity

of the case, even in cerebral malaria the peripheral blood and brain often harbour few parasites [No evidence for this oft repeated statement is provided] The anaemia was measured by the amount of haemoglobin (by the Hellige acid-haematin haemometer) and by the number of red blood corpuscles

Normal figures [see also Haematology, below] for males at the altitude of Nairobi (5,500 ft) are stated to be between 18.7 to 21.25 gm per cent haemoglobin and $5\frac{1}{2}$ and $6\frac{1}{2}$ million red blood cells. African cases of malaria gave an average percentage of haemoglobin of 11.56 gm and 3,387,000 erythrocytes, Europeans, 13.09 gm haemoglobin and 3,860,000 erythrocytes. The two races differed in the number of cases occurring within the normal haematological range, viz 46 per cent of Europeans but only 21.5 per cent of the Africans. The two races differed also in other respects, pigmented leucocytes occurred in 22 per cent of the Africans and in only 4 per cent of the Europeans. Immature blood cells were about four times as common in Africans, the white blood count was significantly higher in Africans (about 13,000 as compared with 8,000) and included many myelocytes. The mononuclear count was found to be little guide to the diagnosis of malaria, in normal Africans, it was found to be 6 per cent, in cases of malaria 8 per cent with very wide variations.

[The author concludes that an appreciable degree of disability arises from the malarial infections, even though the parasitaemia was low. Two queries suggest themselves: was malaria the only cause of the anaemia, and how permanent were the effects?]

P C C Garnham

MASSIAS, C & HAO N D. La cirrhose atrophique du foie paludéenne [Atrophic Cirrhosis of the Liver in Malaria] *Bull et Mém Soc Méd Hôpité de Paris* 1948, Nos 24/25, 826-30 [26 refs]

The authors observed many cases of ascites in highly malarious areas of French Indochina. The clinical picture was that of Laennec's cirrhosis associated with pronounced cachexia and often with well-developed collateral circulation. Autopsies were carried out in some cases and disclosed small hard brown or yellow livers, the dominant lesion in which was annular sclerosis dividing the parenchyma into islands of cells which showed signs of degeneration or hyperplasia or both.

The authors consider that malaria was an aetiological factor of importance in the pathogenesis of the liver lesions. This opinion is based on the exclusion of certain other possible aetiological agents, including alcohol. The authors admit, however, that many other factors, such as nutritional status, may be equally involved.

An unconvincing survey of literature on the subject is given.

B G Macgregor

MONAPATRA G S. Cerebral Symptoms in Benign Tertian Infection. *Indian Med Gaz* 1948, Sept, v 83, No 9, 412-13.

This note refers to a Hindu child of 4 years who was admitted to hospital suffering from a daily pyrexia and rigor, spastic paralysis and aphasia. The spleen was enlarged and palpable. The blood showed 65 per cent haemoglobin and 3,380,000 erythrocytes per cmm.

At the height of the fever on the first afternoon and also on the next day, benign tertian malaria parasites were found in the blood. Careful and repeated examination failed to show subtertian parasites.

The child reacted promptly to intramuscular quinine (after two days on alkalis only, so that the blood slides could be studied). The afternoon fever and rigor stopped on the fourth day and that night the child spoke a few words, and spoke freely next morning. Oral quinine was continued. The child could

The average time of disappearance of the acute attack was 29.14 hours for *crax* and 31.2 hours for *falci-parum* infections.

The *crax* gametocytes disappeared in all the cases noted. They were present originally in 7 cases.

The *falci-parum* gametocytes disappeared in only one of 4 treated cases in which they were present.

There were no cases of severe intolerance to the drug requiring suspension of treatment.

LOZANO MORALES, A. La terapéutica del paludismo por la metoquina. [Treatment of Malaria with Metoquina.] *Rev. Sanidad e Higi. Públ.* 1947 Nov. v. 20 No. 11 1108-11

This is a report of the treatment of 58 patients suffering from *P. vivax* infections with Metoquina (prepared in the Winthrop Laboratories, New York). The duration of the treatment was 5 days. The dose for patients 8 years of age and over was 0.3 gm. (3 tablets) a day. Parasites disappeared from the peripheral blood within 36 hours average maximum 48 hours. All patients were free from fever on the third day of treatment. Thirteen of the 58 patients had relapses: there was no relapse within 30 days of the end of treatment. It is concluded that metoquina is very effective in the treatment of infections with Spanish strains of *P. vivax*.

PATEL, J. C. & MENTA, J. M. Clinical Trials of "Cam-Aqi" in Malaria. *Indian J. Med. Sci.* 1948, Nov. 2, No. 11 675-9

This paper reports the treatment with CAM AQI of 39 patients suffering from malaria in Bombay. Nine had *P. falci-parum*, 22 *P. vivax* and 8 had mixed infections. Some patients received 50 mgm. every 1 hour for 48 hours five doses in all; other received a single dose of 250 mgm. The average duration of fever was 55.9 hours after the commencement of the divided dose treatment and 32.2 hours after the administration of the single dose. Parasites disappeared from the blood within 62 hours (average) in both forms of treatment. The drug appeared to have no action on gametocytes. Twenty patients were observed for 4 months: five of these had relapses after attack periods ranging from 11 to 45 days average 31 days.

(For information regarding the chemical composition of CAM AQI and other clinical trials see this Bulletin 1948 v. 45, 39 and 1947 v. 44 (Feb).)

MENEZES, R. M. & ROSADO, P. N. S. Experiência com novos medicamentos contra a malária no programa da Amazônia. [Experiments with New Antimalarial Drugs in Amazonia.] *Rev. Serviço Especial de Saúde Pública*. Rio de Janeiro, 1948, May v. 1 No. 4 1059-1091. Charts. English summary.

Fifty-four patients suffering from malaria were treated with CAM AQI, 20 with chloroquine, 7 with paludrine and 15 with oxychloroquine. All four

drugs were effective in controlling the clinical symptoms of both *P vivax* and *P falciparum* malaria. In *P falciparum* infections, chloroquine and paludrine failed to free the peripheral blood of parasites in a very large majority of the cases treated with them. CAM-AQI was considered to be the most effective drug of the four: it caused more rapid disappearance of fever and parasites in *P vivax* infections than did the other three drugs; it is effective against both *P falciparum* and *P vivax* infections, a single dose is sufficient to rid the blood of parasites in both types of infection, there are no contraindications to its use.

HALL, D Muriel & TURNER, E E. Structure and Antimalarial Activity Part III Some Benzimidazoles *J Chem Soc* 1948, Nov, 1909-11

HUMPHLETT W J, WEISS M J & HAUSER, C R. Preparation of Ketones from γ -Diethylaminobutyronitrile and Aromatic Grignard Reagents and their Conversion to Diamines Synthesis of Quinacrine Analogs *J Amer Chem Soc* 1948, Dec, v 70, No 12, 4020-23

COVELL, G, NICOL, W D, SHUTE, P G & MARYON, M. Studies on a West African Strain of *Plasmodium falciparum* The Efficacy of Paludrine (Proguanil) as a Prophylactic Agent *Trans Roy Soc Trop Med & Hyg* 1949, Jan, v 42, No 4, 341-6

Attempts have been made at Horton at various times, without success, to infect indigenous forms of *A maculipennis* var *atroparvus* with strains of *P falciparum* from India, E and W Africa, but success was achieved with strains of the same parasite from Sardinia and the Roman Campagna. Recently large numbers of the same species of mosquito were transported to W Africa by air and allowed to feed on children with gametocytes of *P falciparum* in their blood, but could not be infected. Defibrinated blood from a naturally infected child in Lagos was brought back on this trip and maintained in patients by blood inoculation. *A stephensi*, obtained from India, a common malaria carrier there and in the Persian Gulf, was found to be an efficient vector of the Lagos strain of *P falciparum* and was used in the prophylactic experiments described in this investigation.

Four groups of 5 neuro-syphilitic patients infected 9 or more years previously were used in the paludrine tests. Each was infected once weekly for 6 weeks by mosquito-bite or by intravenous injection of sporozoites. Treatment with the drug was begun 3 days prior to infection and was continued for 6 days after the last infection. One group received 100 mgm of the drug daily and a second group half this amount. A third group was given 100 mgm twice weekly and a fourth 300 mgm once weekly. None developed overt malaria during the whole course of the experiment and 18 of them inoculated later with sporozoites of the same strain proved to be susceptible. Three members of the staff were frequently bitten by infected mosquitoes during the experiment while taking 200 mgm of paludrine twice a week and did not experience malarial attacks. Two others while in Nigeria were inoculated intravenously with a salivary gland suspension of a heavily infected mosquito, presumably carrying *P falciparum*. They had taken paludrine daily in 100 mgm doses for some days up to and including that prior to the inoculation and did not become infected. One patient infected like those in the other groups was treated at the same time with 5 grains of quinine hydrochloride daily and another with double this amount. In both cases malarial attacks were suppressed during treatment but both suffered attacks within 2 weeks after it

ended. A group of 5 similar patient infected in the same way served as control and received no drug treatment. All had overt malaria within 14 days. The following is the authors' final observation —

Although paludrine acted as a true causal prophylactic of the *L. m. str.* of *P. falciparum* in each of the regimes under trial, it is considered that for immune person residing in or visiting West Africa should be advised to take not less than mg. 100 of the drug daily for the prophylaxis of malaria. For semi-immune subjects such as native labour forces and locally recruited Government employees, a weekly dose of paludrine mg. 300 is recommended.

D'AMARA, G. B. Tecnica della profilassi antimalarica in Italia. [Anti-Anopheles Control Measures in Italy] *Riv. di Malariologia* 1945 27 v. 27 No. 2, 71-82. English summary (9 lines)

The author passes in review the antimalaria measures that have contributed to the effective control of the disease in Italy in the past. These have outgrown their usefulness. The use of DDT has engendered rather too much optimism as regards the ultimate complete eradication of malaria, by itself alone. DDT is of the greatest value in attacking epidemic malaria, but in dealing with endemic conditions a tightening up of older methods of control with a reorganization of the malaria control service will still be indispensable.

Veronica Wilder

SHOENJA, A. T. Species-Eradication. The Eradication of *Anopheles gambiae* from Upper Egypt 1942-1943. *Bull. World Health Organization* 1945 v. 1 No. 2, 309-52. 28 figs. (16 on 4 pls. 3 maps)

Anopheles gambiae entered Egypt from the Sudan at some time before March 1941 having probably been conveyed there in boats on the Nile. In that year dramatic outbreaks of malaria occurred first near the Sudan frontier then at Assuan, and later as far north as Assut. Enquiry showed that these were associated with a prevalence of *A. gambiae* which had not previously been reported in the country. Breeding places were numerous, particularly in the areas of perennial irrigation though its extent was largely controlled by low temperatures in the winter. In the hot season low humidity probably shortened the average duration of life of the mosquito sufficiently to prevent winter transmission for a large part of the year the epidemics occurring during the limited season when breeding conditions temperature and humidity were favourable.

With the help of the International Health Division of the Rockefeller Foundation a Gambiae Eradication Service was set up on the lines of the equivalent organization which had eradicated the same anopheline from Brazil a few years previously. The system of eradication used was one of organization and not of any special entomological technique. The basis of the organization was the *basic zone* an area of land in which two men working together could treat all water surface with hand-distributed one-per-cent Paris green in dust once a week. The boundaries of these zones, 641 in number were very easily defined so that they were readily identifiable on the ground and on a map. The two men in charge of the basic zone had no other duty than the distribution of Paris green which they did on an organized schedule. It could be readily checked. In each zone were grouped unit men of rank in charge of a foreman, a stable number of these unit men posted with a foreman or engineers in charge and seven of these unit men drawn from the ranks which operated direct under the I. H. D. quarters with its stores and laboratory.

A clear channel for the delegation of responsibility and the transmission of reports was thus provided. Each authority above the basic zone had an inspecting staff the duties of which included checking the anti-larval work and search for adult anophelines, though in pursuance of the policy of "one man, one job" these were carried out by different people. The results of this double check passed through each of the superior organizations which automatically sent inspecting staff to check negative records. By this emphasis on the importance of negative records with supporting data on the amount of searching which had preceded them, a reliable picture could be maintained at the central office where the campaign was directed. Traffic through the boundaries of the eradication zone was disinfested, DDT, then difficult to get, was used on trains and pyrethrum on other vehicles. A therapeutic service was also instituted and in some cases houses were sprayed with pyrethrum to terminate local epidemic conditions.

Work was first started in February 1944. The last specimen of *A. gambiae* recorded was caught in February 1945, but work was continued till the following August and then stopped just before the time of year most favourable to the mosquito. In the following three months, 1,200 men were engaged in survey work examining 400,000 units of breeding area and 60,000 houses each week but no *A. gambiae* were found and eradication was considered complete. Other anophelines were not eradicated (this had not been attempted), and showed a normal seasonal rise.

The campaign is modestly contrasted with that in Brazil and the point is made that conditions in Egypt are less suited to this mosquito than those in Brazil on account of the lower winter temperatures which helped the control work by restricting breeding. In a brief study of past history, it is pointed out that previous epidemics of malaria in this part of Egypt, which have been attributed to an unrecognized prevalence of *A. gambiae*, are explicable on other and simpler grounds. Without attributing previous epidemics to this anopheline it would seem rational on the analogy of known happenings in Brazil to suggest that the actual primary invasion of Egypt took place some years before 1912 and that a "silent period" intervened between the invasion and the epidemics.

The work described in this paper is truly of major importance, being only the second example of anopheline eradication in the world. It should be consulted in the original by all interested in the formation of national policies of malaria control.

G Macdonald

THOMSON R C, Muirhead D D T and "Gammexane" as Residual Insecticides against *Anopheles gambiae* in African Houses. *Nature* 1949, Jan 15, 109-110.

In experiments conducted in West Africa the author had drawn attention to the important effect of DDT treated surfaces as a factor of such importance as to throw doubt on the value of house treatment with DDT as a control measure. (in the *Bulletin* of this *Bulletin* 1948 v 45, 405)

With the use of similar entomological methods the experiments have been repeated by Dr. C. S. M. Tan, in which the DDT in kerosene used in West Africa was replaced by DDT dispersible powder (1 lb. to 1 gallon of water). Large numbers of blood-sucking anophelines were found in the window-trap daily, the majority of them on the floor being only a fraction of those which were caught in the window trap. For at least two months after treatment no blood-sucking anophelines were found inside the hut, creating the impression that a high kill of mosquitoes had been obtained.

These experiments were repeated, substituting Gammaxane (equivalent powder P.530 [now replaced by P.520] for the DDT powder. In contrast to the experience with DDT not a single living anopheles was taken in the wire trap up to thirteen weeks after treatment: numbers of dead *A. gambiae* were collected daily from the floor: the latter lethal action continued for at least three months after treatment. There was no indication of that irritative by drives *A. gambiae* out of DDT treated houses: feeding took place inside Gammaxane-treated hut, but a high proportion of *A. gambiae* were killed before they could bite: especially in the first two or three weeks after treatment. The author emphasises that these experiments were carried out under the conditions for testing an insecticide and that every possible resting place was heavily treated. The Gammaxane powder was applied at the rate of 400 mg. per sq. ft. (34 mgm. gamma isomer per sq. ft.) in a mixture of 1 lb. of P.530 in 1 gallon of water.

[The inference from Dr. Thomson's careful work is that Gammaxane is effective in killing *A. gambiae* which enter dwellings for a blood feed, but DDT is not. The broader aspect of the effect of this method, as a measure of control, on malaria incidence remains to be proved: the prospects are promising.]

GERBERT S. Notes on certain Aspects of the Action of DDT Residual Sprays and on the Partial Treatment of Dwellings as a means of Anti-Anopheline Protection. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1949, Nov. & Dec. No 3 295-7

In houses in an area of 16 square miles in Mauritius, the author collected 12,036 anophelines mostly *Anopheles gambiae*. The houses were then sprayed with residual DDT but no dead mosquitoes were found in daily searches three or four months afterwards. The author's view is that the mosquitoes were aware of the DDT in the houses and did not enter them. He supports this assumption with a theory that micro waves are emitted from the DDT which the mosquitoes can detect by their antennae.

He then gives figures to show that mosquitoes were present in 46 huts in another settlement. The walls of four of these huts were partially sprayed with DDT and an untreated hut was regarded as a control. No mosquitoes were obtained in the four treated huts when they were searched 10-15 days after treatment, but some mosquitoes could still be collected from the control hut.

[Publication of the facts might perhaps be justified, though as present they are lacking in detail: the conclusions drawn from them are unwarranted.]

ANDREWS J. M. & GILBERTSON W. E. Blueprint for Malaria Eradication in the United States. *J. National Malaria Soc.* 1948 Sept. 7 No 3 167-78

Under the original proposal of Dr. Louis Williams it is now decided to try to eradicate malaria from the United States. The procedure decided on is a combined attack on the parasite and on the mosquito and the necessary inter-State and central organisation has been set up for this purpose including arrangements for standardised training. In endemic areas DDT treatment is applied twice a year to houses and other shelters at a dosage of 200 mg. per sq. ft. (7 oz. per 1,000 sq. ft.). An effort is being made simultaneously to improve the diagnosis and notification of malaria cases and to ensure that

proper treatment with effective drugs, and in a few specially selected areas which were previously hyperendemic studies will be made of the intimate epidemiology of the disease and the conditions which may lead to its recrudescence

After one year of work the programme has been put into operation in 80 per cent of the 400 most malarious counties. Although the prospects are thought to be bright, permanent surveillance by specialized staff will be needed to detect recurrence

G Macdonald

LENERT, LOUIA G & LEGWEN, W A A Review of Current Georgia Malaria Control Operations *J National Malaria Soc* 1948, Sept, v 7, No 3, 187-97, 1 fig

Georgia has experienced all phases of malaria control operations from drug prophylaxis to major drainage but since 1945 has relied on DDT as a residual insecticide. Power sprayers and the normal hand-pumped type of machine have been abandoned in favour of modified knapsack sprayers filled with air from a compressed air tank. In the apparatus now standardized the operator carries on his back two cylinders, one holding compressed air which it discharges through a pressure regulator to the other holding emulsion. The air cylinder is refilled as necessary from an air tank carried on a vehicle. DDT is applied as an emulsion at a dosage which has varied from 100 to 147 mgm per sq ft (3.5 to 5.2 oz per 1,000 sq ft), twice in each season with an interval of 10 to 14 weeks between rounds. The heavier dosage is not found to give comparably increased efficiency justifying the increased costs, and the lower dose is now standardized.

Public co-operation, though on the whole satisfactory, has clearly not been as good as it might be and complaints are fairly numerous. Malaria, diarrhoea and enteric appear to have been reduced, the number of reported cases of malaria in the last three years being 461, 109 and 59. Tentative plans include a ten-dollar reward under certain specified conditions to proven cases of indigenous malaria.

G Macdonald

JOBBINS, D M Algunos problemas en el control de mosquitos en la carretera interamericana de Centro America [Some Mosquito Control Problems along the Inter-American Highway in Central America] *Bol Oficina Sanitaria Panamericana* 1948, Sept, v 27, No 9, 819-23. English version 823-6

Increasing motor traffic on the completed or nearly completed parts of the Inter-American Highway in Central America has emphasized the importance of the prevention of mosquito-borne diseases at halting places along the route. Many of the larger centres of population in malarious areas have adopted measures of control that afford a reasonable degree of protection. In the smaller towns of the rural lowlands however, the malaria hazards are considerable. A survey of all such places as are strategically located along the Highway in all countries between Panama and the United States, was commenced in 1943 by the Pan-American Sanitary Bureau. Malaria risks are largely confined to areas below 1,000 feet above 3,000 feet malaria and its vectors are found in very restricted areas in Central America. Isolated foci of malaria in the highlands increased in number during the period of highway construction. This was due to the return of infected labourers to their homes in the hills.

The most important vector is *A. albimanus*. *A. pseudopunctipennis* is probably a secondary vector at high altitudes. Climatic factors in Central America have great influence on mosquito prevalence. Torrential rains in the wet season overload drainage channels built to restrict mosquito breeding and create fresh breeding places. Temperature and humidity during the dry season greatly restrict mosquito breeding on the Pacific slopes. Some adult female species survive only long enough in the dry season to lay eggs. The majority of adult females do not survive long enough in the dry season to be infective.

The Pan American Sanitary Bureau supervised sanitary work in construction camps along the highway mostly in Costa Rica and Nicaragua, where malaria is an important obstacle to labour efficiency. In temporary camps perimeter drainage methods of control could not be justified. In Costa Rica drainage ditching and oil larvicides resulted in excellent control of malaria. Perimeter control was inaugurated in lowland areas in Costa Rica malaria was reduced for from 12 to 40 per cent of all time lost by American labour employed by contractors.

In Nicaragua where large new camps were constructed on the Rama Road to the Atlantic which branches eastward from the Highway near La Manzanilla and Lake Nicaragua, full reliance for malaria control was placed on DDT as larvicide and for the destruction of adult mosquitoes in harrack and other buildings. Control was effective. DDT was used with equal success in other camps in Honduras. Imported malaria cases and carriers were many and required treatment.

In Guatemala between the highland and coastal highway routes which are parallel to the Pacific shore there is a coffee growing area in which Simuliids or Black Flies breed abundantly in swiftly flowing streams. Simuliids were controlled with DDT emulsion concentrate introduced as near the source of the stream as possible was found to be a practical larvicide. Retreatment was necessary at intervals of 1 to 3 weeks. Though effective the practice had to be discontinued. The water in these streams is used as a source of power for drinking, for washing and processing coffee and finally for irrigation. The use of the larvicide raised problems of poisoning water supplies, poisoning human and beneficial insects which come to obtain water from the streams, and power plants in the very dry weather the introduction of toxic materials into the processing of coffee beans and possible damage to plants by insecticide water.

GALVÃO A. L. A. & DAMASCENO R. G. Tempo da ação residual do DDT contra o *Anopheles darlingi*. [Duration of Residual Action of DDT on *Anopheles darlingi*.] *Rev. Serviço Especial de Saúde Pública*, Rio de Janeiro 1948 July v. 2, No. 1 17-22, 1 chart.

The English summary appended to the paper is as follows:—

Studies were made in Belém, Pará, on the duration of the toxic effects of residual DDT on *Anopheles darlingi*. Wooden walls were sprayed with DDT in kerosene solution at 5% leaving a residue of 0.09 Gm. per square meter. It was found that toxic effects of the insecticide disappeared completely by the eighth month of application.

Any observations referring to mortality caused by DDT in mosquitoes maintained without feeding should be made from the 8th to the 14th hour after capture. In the 48th hour the percentage of deaths from natural causes is very high."

PAMPANA, E J Malaria Control by Residual Indoor Spraying with Dichloro-Diphenyl-Trichloroethane (DDT) Survey of Methods for testing Residual Toxicity and of Results *Bull World Health Organization* 1948, v 1, No 2, 253-96, 6 figs [60 refs]

This is an analysis of the methods which could be used to estimate residual toxicity of DDT and a review of the literature on each method suggested. The subjects covered are —

1 Laboratory tests Experimental exposure chamber, wall exposure chamber, recording of data

2 Controlled field tests Determination of the residual toxicity of a given surface, release test, count of resting mosquitoes, determination of the survival rate of exposed mosquitoes

3 Evaluation of reduction in malaria transmission Anopheline density, man-biting rate, sporozoite rate, malaria incidence

4 Available evidence of malaria control by DDT spraying

Details of the methods described are given in full, and include most of the apparatus previously described by SIMMONS and staff [this *Bulletin*, 1946, v 43, 104, 789]. Each of the methods has its appropriate place, outlet window traps should be used and estimations of the survival rate of escaping anophelines made more frequently than in the past.

An appendix deals with the cost of malaria control with DDT residual spray. Insecticide itself is a major part of the cost of any scheme. The price of DDT in the U S A is 0.26 U S dollars a pound [0.45 Kg/m]. Kerosene as a vehicle is always expensive, its cost sometimes amounting to more than that of DDT. The cost of emulsions varies from 42 per cent to 74 per cent of that of kerosene solutions, and suspensions are somewhat cheaper still. There is a useful table which sets out the costs of several campaigns in a manner sufficiently detailed for comparison. They vary from 0.045 to 1.66 U S dollars per head per year. There is also a valuable bibliography.

RODHAIN, J Susceptibility of the Chimpanzee to *P. malariae* of Human Origin *Amer J Trop Med* 1948, Sept, v 28, No 5, 629-31

This paper is a summary in English of the author's work on *P. malariae* in the chimpanzee [this *Bulletin*, 1948, v 45, 978].

SHORTT, H E The Life Cycle of *Plasmodium cynomolgi* in its Insect and Mammalian Hosts *Trans Roy Soc Trop Med & Hyg* 1948, Nov, v 42, No 3, 227-30, 35 figs on pl

This paper describes the life cycle of the monkey parasite *P. cynomolgi* and includes a summary of the recent work on the exoerythrocytic stages [see this *Bulletin*, 1948, v 45, 388, 762, 872]. It is accompanied by a useful diagram, reproduced here, which shows the blood, liver and mosquito cycles.

- 1 Sporozoites from salivary gland of mosquito enter liver cells
- 2 Liver cell containing early stage of pre-erythrocytic parasite
- 3 and 4 Stages in development of the pre-erythrocytic schizont in liver cell
- 5 Fully developed pre-erythrocytic schizont rupturing and releasing pre-erythrocytic merozoites
- 6 Liver cell containing merozoites of exo-erythrocytic cycle of schizogony
- 7-9 Remaining stages in exo-erythrocytic schizogony ending in second generation of merozoites
- 10 Red blood cell of circulating blood
- 11-14 Stages in erythrocytic schizogony in circulating blood
- 15 Fully developed erythrocytic schizont rupturing and releasing erythrocytic merozoites and gametocytes
- 16-21 Repeat time of erythrocytic schizogony
- 22 and 23 Development of male gametocyte or microgametocyte in circulating blood
- 23 and 24 Development of female gametocyte or macrogametocyte in circulating blood
- 25 Wall of stomach of mosquito
- 26 Extragastrelling macrogametocyte producing macrogametes in stomach of mosquito
- 27 Macrogametocyte extruding polar bodies and so becoming macrogamete
- 28 Microgametes free in stomach of mosquito and seeking macrogamete
- 29 Zygote formed by fertilisation of macrogamete by single microgamete
- 30 Ookinete or travelling trichocoele formed by cleavage of zygote. It is about to penetrate epithelial lining of stomach
- 31 Oocyst, formed by ookinete after penetration of stomach wall of mosquito. It lies under elastic membrane on outer surface of stomach
- 32 and 33 Stages in development of oocyst with production of sporozoites
- 34 Rupture of mature oocyst with dispersion of sporozoites most of which enter salivary glands of mosquito
- 35 Salivary gland of mosquito containing mature sporozoites

GRAMICCIA, G. Ricerche sulla infezione degli embrioni di pollo con *Plasmodium gallinaceum* (II Nota) [Infection of Chick Embryos with *P. gallinaceum*] *Riv di Parassit* Rome 1948, Sept, v 9, No 3, 119-28 English summary (5 lines)

In a previous paper the author, in collaboration with G. RITA, described attempts to inoculate chick embryos with *P. gallinaceum*. Heavily infected blood was applied to the chorio-allantoic membrane and a small quantity was injected into the vitelline sac. Only two of 15 chickens acquired infection [this *Bulletin*, 1948, v 45, 158]. Further experiments are now reported. It was found that if the infected blood be drawn from a bird whose internal organs contain exo-erythrocytic forms of the parasite, infection of the embryo was invariably successful. Otherwise only occasional positive results were obtained. The technique adopted is described. *Norman White*

MOULDER, J. W. Effect of Quinine Treatment of the Host upon the Carbohydrate Metabolism of the Malarial Parasite *Plasmodium gallinaceum*. *J. Infect Dis.* 1948, Nov-Dec, v 83, No 3, 262-70, 2 figs [27 refs.]

Results by various investigators suggest that quinine exerts its antimalarial effects by a direct action on the parasites. The present investigation deals with the metabolic effects produced in *P. gallinaceum* by treatment of the infected host with the drug. For this study the activities of the parasites from an untreated host were compared with those from the same host 24 hours after treatment with a single dose of quinine intravenously equivalent to 20 mgm base per kilo. The chickens were inoculated intravenously with infected blood and the final suspension of thrice-washed parasites in Ca-free phosphate saline contained 1 to 2×10^9 parasitized erythrocytes per ml. Oxygen consumption and CO_2 production were measured in a manometric apparatus at 40°C . The small dose of quinine *in vivo* caused a marked change in the metabolism of parasitized cells which, although qualitatively similar, appeared to be greater than that caused by corresponding treatment *in vitro*. The changes noted were recorded in micromoles with respect to 10^{10} square μ of parasite surface area per hour, as used by SILVERMAN *et al* [this *Bulletin* 1945, v 42, 448].

It was found that quinine caused an increase in the rate of disappearance of glucose and of lactate formation, while the oxygen consumption of the parasites was reduced. The increase in O_2 consumption caused by the addition of glucose, lactate or pyruvate to the washed parasitized cells from an untreated chicken was not observed in those from quinine-treated birds. It was concluded that these differences in metabolism resulted from the direct action of quinine on the carbohydrate metabolism of *P. gallinaceum*, after the possible effects of an increase in reticulocytes in the blood and the presence of immune factors had been considered. Quinine did not alter the RQ [respiratory quotient] of parasitized erythrocytes metabolizing glucose, but when lactate and pyruvate were used as substrates after quinine treatment O_2 uptake and the utilization of these substrates was decreased, while the RQ and O_2 /substrate ratios were unaltered. The results of quinine treatment on the oxidation of the three substrates mentioned suggest that in the anaerobic phase their breakdown is not affected by the drug, while in the aerobic phase the complete oxidation of pyruvate via the tricarboxylic acid cycle is inhibited [cf SILVERMAN *et al* above]. Since KELSEY *et al* [this *Bulletin*, 1944, v 41, 11] have shown that quinine disappeared from the blood in a few hours, the present results indicate that the inhibition of carbohydrate metabolism by quinine is irreversible or that an effective metabolite of this substance continues to act.

TRAGER, W. The Resistance of Egg-laying Ducks to Infection by the Malaria Parasite *Plasmodium lophurae*. *J Parasitology* 1949 Oct v 34 No 5 389-93 1 fig. [10 refs.]

It was noticed that a certain number of adult ducks infected with *P. lophurae* failed to respond in the usual manner to the disease: the parasites were low in number and abnormal in morphology. The meaning of this was indicated by repeating the experiments on 3 groups of ducks 6-7 months old. One group was composed of males, the second group of females with inactive ovaries, and the third group of females with active ovaries. They all received equivalent and very heavy doses of *P. lophurae*. Most of the ducks in the first two groups developed heavy infections, while the egg-laying group showed a poor response: the parasites not multiplying in nine out of 10 duck in this last group.

The author then proceeded to correlate this finding with the amount of biotin or biotin-actinoids in the plasma of the infected birds. A high biotin content was found to be associated with egg-laying activity and with a relative resistance to the malarial infection: male ducks had the lowest biotin concentrations and conversely were very susceptible to the disease.

THOMPSON, P. E., with the technical assistance of Anita RAYNES, D. L. BROWN & Betty L. LILLIGRAN. On the Ability of *Plasmodium lophurae* to acquire Resistance to Chloroquine, Camoquin and Chloroquine. *J Infect Dis* 1948 Nov-Dec. v 63 No 3 240-55 [15 ref.]

The development of acquired resistance to paludrine (chloroquine) in *P. gallinaceum* was recently described (this Bulletin 1947 v 44 p. 870 1948, v 45 158). A similar resistance has now been shown to occur in the case of *P. lophurae* but could not be obtained with Camoquin (SN 10751) or with chloroquine both 4-aminoquinoline derivatives. White Leghorn chick 4 to 8 days old were inoculated intravenously with parasitized blood and the drug was administered in the diet for some hours previous to infection. They were maintained on a light and dark schedule for alternate periods of 4 hours in order that the intake of drug should be as constant as possible. The level of drug was such as to cause a 90 per cent. suppression of the infection. Under these conditions the parasites were kept in almost continuous contact with it. Subinoculations were made twice weekly over a period of 211 days and included 60 passages. When testing for acquired resistance suppression of infection to the extent of 50 per cent. or near the peak of parasitaemia was accepted as indicating that a drug was still effective. Within 28 days in which 8 passages were made resistance became evident in the paludrine-treated bird and was correlated with the morphological appearance of the parasites. The resistance developed only gradually in contrast to that obtained with *P. gallinaceum*. The resistance to paludrine did not affect the result of treatment with plasmoquine (amaquin), quinine, telmepoquine, chloroquine or Camoquin. Experiments on the persistence of resistance after mosquito transmission were not made.

BARNGR, P. & FILSH, M. K. Contribution à l'étude des mélanges d'alcaloïdes du quinquina. A Study of Mixtures of Cinchona Alkaloids. *Ann Parasit* 1948 Oct v 75 No 4 329-37

In a previous paper (this Bulletin 1944 v 41 p. 103) the senior author with THOMAS reported from tests carried out on canaries infected with *P. relictum* that total alkaloid from different cinchona barks gave better therapeutic results than quinine alone. The result was poor however when the quinine

was removed. They have now found that certain combinations of the four main alkaloids in pairs give more favourable results in blood-induced infections of *P. relictum* and *P. gallinaceum* than quinine alone. It is possible that a synergistic effect results from the action of the alkaloids in combination on different stages in the life cycle of the parasites. Cinchonine seems to have a special mode of action, since its effects are produced at very much lower plasma concentrations than in the case of the three other alkaloids. In the case of *P. relictum*, the activity of each alkaloid was similar. There appeared to be a synergistic action between cinchonidine and quinine. Under the experimental conditions the results confirmed the previous findings that the activity of the total alkaloids from different barks is equal or superior to quinine or the other pure alkaloids. The percentage of quinine in the total extract did not appear to determine the activity of the mixtures. Similar experiments with mosquito-transmitted infections appear desirable.

ASFANJO, C. F., FRIEIRE DE GUZMÁN, A. R., MAYORAL DE ASFANJO, A. G. & DE TOHIZ CANDAL, J. G. A Chemical Study of the Molinillo Plant (*Leonotis nepetifolia* L.), with special reference to its Seed. *Puerto Rico J. Pub. Health & Trop. Med.* 1948, Sept., v. 24, No. 1, 44-56, 2 figs. [Refs. in footnotes.] [Spanish version 57-68.]

Chick and canary tests gave negative results for antimalarial activity with the exception of the seed that showed a slight activity."

PARAENSE, W. I. Observações preliminares sobre o ciclo exoeritrocitário do *Plasmodium juxtanucleare* Versiani e Gomes, 1941. [Preliminary Observations on the Exoerythrocytic Schizogony of *Plasmodium juxtanucleare* Versiani and Gomes, 1941.] *Vem. Inst. Oswaldo Cruz*, 1947, Dec., v. 45, No. 1, 813-23, 1 graph & 15 coloured figs. on pl. English summary.

BARRITO (this Bulletin 1944, v. 41, 732) described briefly exoerythrocytic schizonts of this malarial parasite of the domestic fowl. He observed the forms solely in the cerebral capillaries 44 to 52 days after inoculation, and the schizonts he figured were small bodies with a maximum of 19 blocks of chromatin. Other observers in South and Central America have hitherto failed to confirm this work, but now Paraense has been successful in obtaining exoerythrocytic forms of a different type from those described by Barreto. He recovered the strain from a fowl bought in the Minas Gerais State of Brazil and maintained it in Light Sussex Rhode Island and Leghorn chicks. The infection was passaged intravenously and the birds were sacrificed at different intervals after inoculation. Smears were made of the spleen, bone marrow, liver, lungs and brain, and exoerythrocytic schizonts were found in these organs in numbers following the above order, being most numerous in the spleen (up to 5 parasites per field under the 1720 μ objective) and fewest in the brain. The schizonts were first seen 9 days after inoculation and were most plentiful during the third week. If quinine (150 mgm. per kilo druck) is administered after the fifth day of the patent period, parasitaemia is depressed to 4 per cent. or less, but the chicks die from the exoerythrocytic infection.

The author does not describe in the text the morphology of these parasites, but illustrates them by a coloured plate. In this plate may be seen rather small, oval, oval, or rectangular or endolothal cells in contrast with apparently a many-sided meronts. Mosquito transmission of *P. juxtanucleare* has still to be effected by the erythrocytes of the parasite, etc. etc. (see report described).

SERGEANT Ed. & SERGEANT Et. *Haemoproctus wexron* nov. sp. parasite du moineau algérien retrouvé chez des canaris élevés en cage [*Haemoproctus wexroni* sp. nov. Parasite of the Algerian Sparrow recovered in Cage-Reared Canaries.] *Arch Inst Pasteur d'Algérie* 1948 Dec., v 78 No 4 394-6 2 figs.

A *Haemoproctus* was first found in parrots by GRASSI and FERRITI in 1880 in Sicily. It was redescribed by the present authors in 1907 from Algeria, while WEXRON in 1911 discovered the asexual forms in the sparrows of Bagdad. The species has remained nameless until now when it receives the name of *H. wexron*. It differs from most other forms by a marked irregularity of outline. The younger gametocytes are small oval bodies.

Large numbers of canaries are kept in cages in Algiers. In the neighbouring trees are thousands of sparrows. It is not surprising therefore that the arthropod-borne parasites of the latter eventually infect the caged birds. The sparrows are heavily infected with *Haemoproctus* as are 5 per cent. of the canaries. 100 per cent. of sparrows and 4 per cent. of the canaries show *Plasmodium relictum*. 13 per cent. of the sparrows and 0.04 per cent. of the canaries show *Eusporis sergenti*. The indigenous sparrow thus constitutes a reservoir of the local parasites and this situation is paralleled in human beings, the non-immune immigrant becoming infected with malaria and other endemic diseases.

[This paper is doubly *memorandum* since it was written two of the chief characters have died, Dr Etienne SERGEANT in August 1948 and Dr C. M. WEXRON in October.] P. C. C. Garnham

NEGRINE, A. & ROMÁN, J. Present State of Chagas' Disease Surveys In Chile
Amer J Trop Med 1948, Nov, v 28, No 6, 835-9

This is a report of a survey carried out between August 1944 and December 1947 in the Provinces of Tarapaca, Atacama, Coquimbo, Aconcagua, Valparaíso and Santiago. 12,581 persons were examined by xenodiagnosis and in many cases blood was taken for serological tests. From examination of random samples in the endemic zones an average of 12 per cent was found infected with *T. cruzi*. During the period of investigation 1,631 human infections have been found. The distribution by Provinces is given in a Table, the chief were Santiago (734) and Coquimbo (441). Machado Guerreiro reactions were performed in 8,142 individuals from endemic zones and 17 per cent proved positive and another 10.9 per cent were suspicious (2-plus). [Some authors dispute the specificity of this test, so the authors themselves tried it on 2,000 sera from University students with no suspicion of any epidemiological antecedents of Chagas's disease, only two were positive]. Of 3,182 domestic animals, dogs and cats, tested by xenodiagnosis, 126 or 13.4 per cent, were positive, no rabbit or guinea pig was positive out of 126 examined and only 11 out of 698 "wild animals" and 8 of these were the indigenous Chilean rodent, *Octodon degus* Molina.

They have also examined 20,614 tritomidæ from different endemic zones, the percentage of infection varied, naturally from zone to zone, but, of the whole 9,164 (44 per cent) were infected—sufficient to explain the widespread infection throughout the country. For prophylaxis, the main object is of course, to build vinchuca proof houses, but in the meantime insecticides play a major part and DDT has been largely used. 5 per cent in kerosene, or of this strength prepared from a basic solution in xylol added to Triton X-100 as a detergent. 830 houses have been sprayed with 1.047 gm per house. Flies, fleas and bed bugs have practically disappeared. The results as regards Tritomidæ were not so good unless the infestation was very slight but they were reduced below the initial levels. With Gammaxene the results were practically the same as those with DDT. Chlordane (or Oltachlor) $C_{10}H_6Cl_6$, even in a 5 per cent concentration had little noticeable action on tritomidæ.

H. Harold Scott

The results of inoculating the Ber strain in man were surprising. As recently isolated strains of *L. tropica* are fatal to Syrian hamsters but produce only harmless local lesions in man. It seemed likely that the Ber strain, which was non-infective to hamsters would be similarly harmless to man. It was found, on the contrary, that when it was inoculated intradermally in two human volunteers, both developed lesions containing numerous LD bodies. Both cases also gave a positive leishmanin reaction. Cultures from these cases were non-infective to hamsters.

In one case originally infected in 1925 with flagellates obtained from a wild caught sandfly, a lesion developed which was cured spontaneously in about two years. This case proved immune to frequent subsequent attempts at re-infection and the skin test remained constantly positive between 1927 and 1938. In 1946 a phenolized suspension of the Ber strain was inoculated intradermally and produced an erythematous area of 4 in. in diameter at 48 hours which began to recede after 72 hours.

Five days after this inoculation living flagellates of a strain known to be infective to man and hamster were inoculated. This inoculation produced an erythema of 4 in. diameter with a central necrotic area. There was a temperature reaction. After 24 hours, a culture from the necrotic area yielded growth, results for leishmanin and was bacteriologically sterile. Later cultures remained sterile both as regards leishmanin and bacteria. The affected area developed lymphangitis and blisters, the former persisting for a week. The necrotic area became haemorrhagic and eventually healed leaving a scar. The sequence of events would appear to justify the conclusion that it was an example of an Arthus reaction produced by a protozoon.

The Ber strain showed a reduced infectivity for *Phlebotomus papatasi* as compared with recently isolated strains. H. E. Shortt

AUERBACH S. H. & BUCKHOLD, R. R. Cutaneous Leishmaniasis in the United States. Report of a Case in a Veteran. *Am J Trop Med* 1948 Nov v 28 No 6, 831-4 3 figs.

The thirty first case of cutaneous leishmaniasis reported from the United States and Canada is presented. All were exogenous. The patient was returned veteran who had been exposed to infection in the Mediterranean area. The disease responded satisfactorily to radiation therapy.

RITTERSON, L. L. & STACHLER, L. L. Protein Intake and Leishmaniasis in the Hamster. *Proc Soc Exper Biol & Med* 1949 Jan. v 51 147-50 2 figs.

Protein intake influences the course of leishmaniasis in the hamster. deficient diet is due to earlier emaciation and death. Excess dietary protein seems to favour survival.

FEVERS OF THE TYPHUS GROUP

RICCIARDI, C. & COZZIGLIOSI, E. L'opera dei Medici Italiani. La lotta contro il dermatite in Etiopia (1937-1947). The Work of Italian Medical Men in the Campaign against Typhus Fever in Ethiopia. *Ann Med* 1948 Nov v 3 No 11 293-303 4 figs.

An editorial preface to this long article is followed by a description of the work of the Italian medical staff in Ethiopia. The work is described in a clear and organized fashion. The Italian medical staff

This effort is described as all the more noble, and even heroic, because it was carried out in conditions of disturbance associated with a lost war and of discouragement due to uncertain future prospects

In such circumstances it is certainly surprising to find that about 90 articles on the typhus fevers of Ethiopia have been published or prepared for publication during the period. Nearly all of these have been written by the authors and Dr G MARIANI

Many references to the work will be found in this *Bulletin*

Louse-borne typhus was by far the most common form of the disease, but the occurrence of "benign flea typhus" has been definitely established, and it is said that both tick typhus and mite typhus have been clearly identified on clinical grounds, supported by serological and laboratory studies, which though not yet complete, are regarded as justifying the authors in concluding that the diseases occur in Ethiopia

MONTESTRUC E Contribution à l'étude des rickettsioses à la Martinique (Comportement des sérums des sujets normaux, des fébricitants et des femmes enceintes vis-à-vis des *Proctus* OΛ19, OΛ2, OXK, OAL et des rickettsies des typhus épidémique et murin) [A Study of the Rickettsial Diseases of Martinique (Well-Felix and Rickettsia-Agglutination Reactions among Normal Persons, Febrile Patients, and Pregnant Women)] *Arch Inst Pasteur de la Martinique* 1949, Jan, v 2, No 1, 3-20

CIACCIO, G Essais d'inoculation de *Rickettsia prowazeki* et *Rickettsia mooseri* chez les insectes Étude des anticorps spécifiques [Experiments in Inoculation of Insects with *Rickettsia prowazeki* and *R mooseri* Study of Antibodies] *Ann Inst Pasteur* 1948, Dec, v 75, No 6, 585-6

The following is a translation of the author's summary —

Pathogenic rickettsiae (*R prowazeki* and *R mooseri*) can be adapted to insects other than those which are ordinarily their hosts. The chrysalis of *Bombyx mori* and the larva of *Tenebrio molitor* support the survival of the virus, but nevertheless do not develop anti-rickettsial agglutinins [see also this *Bulletin*, 1947, v 44, 703]

H J O'D Burke-Gaffney

GALLARDO, F P & FOX, J P Infection of Guinea Pigs with Massive Doses of Rickettsiae of Epidemic and Murine Typhus *J Immunology* 1948, Dec, v 60, No 4, 455-63 [12 refs]

The authors have studied the effects produced by the inoculation of massive doses of epidemic and murine rickettsiae into guinea-pigs by the intraabdominal and intracardiac routes. Highly concentrated suspensions of infected yolk sacs and cotton-rat livers were employed, these caused severe, often fatal, disease, especially when administered by the intracardiac route.

The disease was more severe in large guinea-pigs than in small, and younger, ones, the authors suggest that this difference in susceptibility may be related to the greater severity of typhus fever in elderly patients.

Although the incubation period after massive doses was only two or three days the illness was a true infection, not an intoxication of the kind observed in mice inoculated with large doses of rickettsiae.

The authors believe that the employment of large doses is likely to be useful in the study of the chemotherapy of typhus fever and in the development of improved methods of carrying out serum-neutralization tests.

Among the four strains of epidemic rickettsiae employed was the "E" strain originally isolated in Madrid by CLAVERO and PÉREZ GALLARDO in 1943 [this *Bulletin*, 1944, v 41, 24], this was found to have maintained its low virulence—

through 239 passages in embryo chicks, it also produced a lower degree of immunity in guinea pigs than the virulent strains commonly used. (See this *Bulletin* 1919 v 48 n°4)

The infections caused in guinea pigs by massive doses were less severe in the hot season (June) than in the cold season (January and March)

D'IGNAZIO C & MITCHELL P S. Rara complicanza oculare in un caso di dermatite. [A Rare Ocular Complication of Typhus.] *Acta Med Italica* 1918 Dec., v 3 No 12, 315-18. English summary (3 lines)

The English summary appended to the paper is as follows —

"The authors describe a case of optical neuritis in a patient suffering with typhus and point out some considerations about this rare complication.

MOORE, H. On the Nomenclature of the Agent of Murine Typhus. *Amer J Trop Med* 1918 Nov v 29 No. 6 841-3. [18 refs.]

The author raises strong objections to the proposal by PHILIP that the name *Rickettsia moorei* should be changed to *R. typhi* or *R. prowazeki* var *typhi* [see this *Bulletin* 1943 v 40 828]

The reason given for making this proposal is that WOLBACH and TOMP in 1930 gave the name *Dermacentor oxeus typhi* to the organism found in a form of Mexican typhus which Wolbach, in a personal communication to Philip, said he believed to have been probably of the murine type.

Moore insists that it would have been utterly impossible for Wolbach to have made a reliable diagnosis of murine typhus on the strength of the available evidence which consisted in the histological characters of sections of skin of few patients. Moore mentions a case in which expert (of the highest standing in 1931) made a confident diagnosis of epidemic typhus on the strength of a complete histological examination, but later had to admit that the disease was probably Rocky Mountain spotted fever. Reasons are given for believing that the cases seen by Wolbach were far more likely to have been of the epidemic rather than of the murine type so that the name given by Philip has no standing." [See the comment on the abstract above]

DIAZ RIVERA, R. S., GUZMAN ACOSTA, C., COLLAZO P. J. & DOMALUS LERON, A. Effect of Para Amino Benzoic Acid on Murine Typhus. A Clinical Study of 60 Cases. *Amer J Med Sci* 1949 Jan v 17 No 1 13-20 1 fig [18 refs.]

"During the past two years 33 patients suffering from murine typhus were treated by large doses of PABA and 27 patients picked at random were kept as untreated controls.

Treatment was started, on the average 8.3 days after the onset. The only effect on the rash was that it disappeared more rapidly in the treated. Two of the treated had severe nausea and vomiting but so also had some of the untreated controls.

Improvement in the general condition was usually evident within one or two days, the average duration of the fever was 8.7 days in the treated, and 15 days in the control, patients. There was no death in either group.

In 14 cases the treatment was started after the 7th day, yet in 6 of these the results were favourable.

The dosage was 4.0 gm initially, then 2.0 gm every two hours till convalescence was established. The total amount given was as much as 219 gm in some cases.

FITZPATRICK, Florence K. Effect of an Analogue of DDT on Experimental Murine Typhus. *Proc Soc Exper Biol & Med* 1949, Jan, v 70, No 1, 90-91.

"The nitro analogue of DDT when given in the diet for 7 days to mice infected with murine typhus resulted in a degree of survival on the 7th day equal to that obtained when 4 times the amount of PABA was administered. After the 7th day, when the drug was withdrawn, more PABA-treated mice succumbed, indicating that the nitro analogue is a better rickettsiacidal agent. The oral toxicity of the compound for mice appears to be of a low order."

RUIZ SANCHEZ, F & RUIZ SANCHEZ, A. El tratamiento del tifo exantemático con aureomicina. Reporte preliminar [Treatment of Typhus Fever by Aureomycin]. *Medicina Mexico* 1948, Dec 25, v 28, No 570, 521-7, 5 graphs.

Five cases of typhus fever, probably of the murine type, were treated by oral administration of aureomycin. The daily dose was 300 mgm per kgm of body weight given in divided doses every three hours. In the earlier cases the treatment was continued for several days, but later it was found that treatment for one or two days was equally effective. In every case the response to treatment was prompt and satisfactory.

The only signs of intoxication were occasional nausea, vomiting and diarrhoea, but these soon disappeared and did not necessitate interruption of the treatment.

SMADEN, J E. Chloromycetin in the Treatment of Typhus Fevers. *Bull U S Army Med Dept* 1949, Feb, v 9, No 2, 117-23, 3 figs.

This paper consists chiefly of a succinct summary of recent work on the treatment of fevers of the typhus group by chloromycetin. This work, most of which was done by the author, has been dealt with in recent numbers of this *Bulletin*.

Reference is made to a trial of the drug as a prophylactic: a group of 40 volunteers exposed to special risk of infection by scrub typhus in a hyperendemic area near Kuala Lumpur remained free from clinical symptoms during the period of exposure and for a week after ceasing to take the drug, but "thereafter, a considerable proportion" of them were attacked so that the drug seemed to have acted as a temporary suppressive.

Among 24 control persons exposed to the same risk there were 17 cases of the disease with onset between the 12th and 22nd day after initial exposure.

Further studies on the chemoprophylaxis of the disease are being initiated.

STOKER, M. G. P. Serological Evidence of Q Fever in Great Britain. *Lancet*, 1949 Jan 29 174-p. [14 refs.]

Among 24 sera from sporadic cases of atypical pneumonia, three were found to give positive complement-fixation reactions against an American and an Italian strain of Q fever antigen supplied by Dr. Herald Cox.

Two of the reacting patients had been living at a Royal Air Force Station near Salisbury. Wiltshire for some time before the onset, which was in April, 1949 in one case and February, 1948 in the other. There had been only one other case of atypical pneumonia at this station during the first half of 1948 but no sample of serum could be obtained.

The third patient was admitted to the Kingston County Hospital, near London in June 1949; this patient and one of the other two had never been abroad so that the infection must have occurred in England. The titres of the reactions were 1-40 to 1-80 and the result of the test were confirmed by Dr. Ross Gould at the Army Medical School, Washington in both of the sera submitted to him.

VISCHER, W. A. Gehäuftes Auftreten von Q-Fieber in einer Rekrutenschule [An Epidemic of Q Fever in a School for Recruits.] *Schweiz med. Woch.* 1949 Feb 19 v. 79 No. 7 137-R.

During the months of March and April, 1944 an explosive outbreak of Q fever occurred in a school for recruits at Monte Ceneri in Switzerland. There were 56 cases among 440 young recruits.

The source of infection could not be discovered; it was suspected that inhalation of infected dust was responsible because the outbreak occurred in fine and dry weather. Some cases were found to have occurred among the inhabitants of a neighbouring town which was visited by the recruit when off duty.

BECK, M. D., BELL, J. A., SHAW, E. W. & HUTCHINS, R. J. Q Fever Studies in Southern California. II. An Epidemiological Study of 300 Cases. *Pub. Health Rep. Wash.* 1949 Jan 14 v. 64 No. 41 561 map. [71 refs.]

This study formed part of a combined investigation by the National and California Health Services into the epidemiology of Q fever.

A detailed survey was made of the epidemiological conditions associated with 300 proved cases of the disease in the Los Angeles area.

The disease occurred throughout the area at all seasons and year after year. Most of the patients were adult males. Transmission of infection appeared to be associated with one of the following circumstances: (1) Employment in the dairy or livestock industry; (2) residence near a dairy or livestock yard; (3) the use of raw milk by the household.

One of these three factors could by itself have been responsible for the infection in more than half of the cases but in 78 per cent there was clear evidence that one or more of the factors could have been concerned and this percentage was greatly in excess of that applying to the rest of the population of the affected area. Further studies are in progress to discover the relative importance of each factor.

A useful bibliography supplies references to 28 papers on Q fever.

JELLISON, W L, HUEBNER, R J, BECK, M D, PARKER, R R & BELL, E J
Q Fever Studies in Southern California VIII Recovery of *Coxiella burnetii* from Butter made from Naturally Infected and Unpasteurized Milk *Pub Health Rep* Wash 1948, Dec 31, v 63, No 53, 1712-13

High-titre complement-fixation reactions against *Coxiella* [*Rickettsia*] *burnetii* were found to occur in guinea-pigs inoculated with refrigerated butter made from the raw milk of cows infected with Q fever. The butter was still infective after being kept in the refrigerator (below 0°C) for 41 days. A strain of the rickettsia from the butter was isolated and established in a guinea-pig.

JANTON, O H, BONDI, A, Jr & SIGEL, M M **Q Fever Report of a Case in Pennsylvania** *Ann Intern Med* 1949, Jan, v 30, No 1, 180-84, 1 fig [20 refs]

"The first report of a serologically authenticated case of naturally acquired Q fever in eastern United States is presented. The clinical features are discussed in detail with emphasis placed on the consideration of this disease in the differential diagnosis of respiratory disorders. The possible mode of transmission is discussed."

DE RODANICHE, E C & RODANICHE, A **Studies on Q Fever in Panama** *Amer J Hyg* 1949, Jan, v 49, No 1, 67-75 [24 refs]

Sera of 26 patients, including 17 diagnosed as suffering from atypical pneumonia, were tested by the complement-fixation reaction for Q fever. Only three gave a significant reaction, and from one of these a strain of *Rickettsia burnetii* was isolated.

In the Gorgas Memorial Hospital nine workers were engaged in the study of Q fever rickettsiae from March, 1947, but no case of obvious infection occurred till February, 1948, when one of them had a severe attack and a strain of *R. burnetii* was isolated from his blood. This worker was also engaged on field work in the course of which he was often bitten by ticks, so that infection may not have been acquired in the laboratory.

Four of the other workers were found to have positive fixation reactions at titres of 1-128, 1-64, 1-16, and 1-8, respectively, but none of them had suffered from any illness suggestive of Q fever. The worker with a titre of 1-128 was known to have had a negative reaction about four months previously so it appeared that he must have had a sub-clinical infection.

John W D Megaw

PHILIP, C B **Observations on Experimental Q Fever** *J Parasitology* 1948, Dec, v 34, No 6, 457-64

Most of the experimental work described in this paper was carried out before the recent war. Some of the chief findings are as follows.

Q fever infection could not be transmitted, even mechanically, by the bite of *Aedes aegypti* from infected to susceptible guinea-pigs. The mosquitoes were allowed to feed on the test guinea-pigs immediately after making the infected blood meal and also 10 to 30 days afterwards.

Infection rapidly disappeared from the bodies of the mosquitoes, as was shown by the failure to infect guinea-pigs with suspensions of the guts of the insects after an infecting feed.

Suspensions of infected *Dermacentor andersoni* were infective to guinea-pigs in dilutions as high as 1-500,000 millions, and in very high dilutions even after

passage through Berkefeld N and W candles. Dried faeces of infected *D. andersoni* were still infective after storage for 596 days, and after storage at room temperature, with 70 per cent. humidity, for nearly six years they still showed recognizable organisms and produced immunity in inoculated guinea-pigs though strains could not be isolated from the animal or by yolk-sac culture.

Infected faeces of ticks and suspensions of spleens of infected guinea-pigs caused infection in guinea-pigs by application to the unbroken skin. Powdered tick faeces dusted into the nostrils, eyes or mouth, of guinea-pigs caused infection. *D. andersoni* infected during the nymph stage and kept for 65 and 177 days at 35°F. were still highly infective. This result is in contrast with what happens in tick infected with *R. rickettsi* which need a "reactivating" blood meal before becoming infective in similar circumstances.

Infection was recovered from house-flies caught in a room in which infected guinea-pigs were kept, but house-flies did not appear to be capable of transmitting infection because when given free access at the same time to infected guinea-pigs in one set of cages and susceptible guinea-pigs in other cages no transmission occurred.

Flies fed on infected tick faeces and on infected spleen pulp of guinea-pigs became contaminated with the rickettsiae; this was shown by the production of the disease in guinea-pigs inoculated with suspensions of the bodies of the flies.

WOLFE D. M. & HORNFIELD Lottie. With technical assistance of LOIS GALLIX. *Conglutinating Complement Absorption Test compared with Hemolytic Complement-Fixation Reactions using Q Fever Immune Bovine Serum.* *Proc Soc Exper Biol & Med.* 1948, Nov. v. 69 No. 2, 251-5.

The essential difference between the Conglutination Complement Absorption Test and the ordinary complement-absorption test is that in the former clumping instead of haemolysis of red cells serves as an indicator of the presence of unabsorbed complement.

The occurrence of conglutination was first described by BORDET and STRENG in 1909 and a test for glanders based on this phenomenon has been worked out by HOLT and COCHRAN in 1947. The latter workers observed that clumping of sheep red cells occurs when a suspension of them is mixed with heat-inactivated bovine serum and fresh unheated serum of a horse, dog or cat. The bovine serum contains a natural antibody which sensitizes the sheep cells and also conglutinin; the fresh serum contains complement.

Technical details of the application of the test to the detection of Q fever in cattle are given in the paper.

From the tests already carried out the authors conclude that the reaction is likely to prove more sensitive and more specific than the complement absorption test in common use. Further studies are said to be in progress.

John H. D. Meyer

SHEPARD C. C. Q Fever: a Serological Survey of Bovine Serums in the United States. *Amer J Trop Med.* 1948 Nov. 28 No. 6 849-55 (11 refs.)

Through the organization which exist for testing cattle for brucellosis it was possible to obtain samples of serum from 1783 cattle from 37 States of the U.S.A. other than California.

Complement-fixation tests showed that 77 of the cattle were or had been infected with Q fever. Positive samples originated from the following States — Pennsylvania, Wisconsin, Minnesota, Missouri, North Dakota, Nebraska, Kansas, Virginia, Kentucky, Mississippi, Texas, Colorado, New Mexico, Arizona,

Washington, and Oregon. In Pennsylvania there was only one positive among 99 samples, in Nebraska, Missouri and Wisconsin there were three positives among 48 to 50 samples, in all the other States mentioned there were either one or two positives in 47 to 50 samples.

Only two of the positive samples came from the eastern one-third of the U S A.

A rickettsia-agglutination test was carried out on a large number of random samples of the sera with the surprising result that there were 68 per cent of positive reactions at titres of 1-5 to 1-125. These reactions were regarded as non-specific and as being due to the presence of "natural" antibodies.

In a footnote the author states that since this paper was submitted for publication the official name of Q fever rickettsia has been changed from *R. burneti* to *Coxiella burneti*.

[No mention is made of the official agency by which this change was decreed. The change was proposed by PHILIP in 1943 (see this *Bulletin*, 1943, v 40, 828). In the same article Philip proposed that the name *R. mooseri* should be changed to *R. typhi*, this proposal has been severely criticized by MOOSER (see below). Philip also advocated the use of the name *Dermacentroxenus rickettsi* instead of the more usual *R. rickettsi*.

It is to be hoped that definite evidence of the necessity for these changes will be provided, otherwise there may be passive resistance to their acceptance.]

There was apparent response to streptomycin.

YELLOW FEVER

HADDOW, A J, SMITHBURN, K C, DICK, G W A, KITCHEN, S F & LUMSDEN, W H R. Implication of the Mosquito *Aedes (Stegomyia) africanus* Theobald in the Forest Cycle of Yellow Fever in Uganda. *Ann Trop Med & Parasit* 1948, Sept, v 42, No 2, 218-23 [12 refs]

As the result of their previous studies of the epidemiology of yellow fever in Uganda, the authors concluded that the mosquito *Aedes africanus* Theobald is probably the main vector which transmits the infection among the arboreal monkeys. Yellow fever virus was isolated from a mixed lot of *Aedes* mosquitoes belonging to twelve species, including *A. africanus*, in 1944. Further large catches in 1944 and 1945 failed to yield virus. The method of investigation was then altered. Rhesus monkeys were placed on 16 platforms in different areas of the forest at the level of the canopy. The monkeys were tested for

neutralizing antibodies beforehand and at monthly intervals. Temperatures were taken daily. None of these animals contracted yellow fever. Further mosquito catches and 13 monkeys on platforms gave negative results in 1946. In 1947 it was found that 4 *A. f.* did not readily enter the type 1 monkey cage used, so that monkeys were then secured uncaged on 39 platforms. The monkeys all remained negative in 1947 in Bwamba where most of the platforms were, but one monkey stationed at Zika in the forest on the shore of Lake Victoria became infected and recovered. On the other hand mosquito catches were negative in Zika but the virus was isolated in December 1947 from a batch of 4 *A. africanus* from Bwamba.

F. O. MacCallum

HADDOW, A. J. & DICK, G. W. A. Catches of Biting Diptera in Uganda, with Anaesthetized Monkeys as Bait. *Ann. Trop. Med. & Parasit.* 1948 Dec. v. 4, No. 34 271-7

The authors continue their studies on mosquitoes in Uganda, giving particular attention to those species which live in forest canopy [this *Bulletin* 1949 v. 48 177]. They are much interested in *Aedes fuscans* which lives much in treetops and has been shown to contain virus.

They here describe experiments using monkeys (*Cerc. pileatus* of two separate species and Indian rhesus monkey) narcotized with nembutal. They only record mosquitoes which actually bit the monkey, which were exposed at various levels from the ground to the treetops. In each of three catches the most frequent biter was *Aedes africanus*. It forms a higher proportion of the catch on monkey than on man (the converse being true of *An. phlebotomus*). They record fifteen species of mosquito and one *Chrysops* biting monkeys.

P. I. Burton

DENGUE AND ALLIED FEVERS

KAWAMURA, R. FUKUTSUKI, S. ITOH, T. ITOH, H. TAKAGI, S. & OBATA, Y. Kulturelle Ergebnisse im bebrüteten Hühneret von Denguevirenter Rangoon Typ. Results obtained by the Culture of Dengue Virus (Rangoon Type) in Embryo Chick. *Wissenschaftl. Ztschr. Exper. Med.* 1947 June 79 No. 1 1-28 4 charts & 8 figs. on 3 pls. (2 coloured). 17 ref.

The authors have maintained a strain of dengue virus in embryo hick through 20 passages, and have transmitted infection to human being by inoculation with suspensions of the chorioallantoic membranes of infected embryo chicks of the 14th passage.

Modified attacks were also produced in Formosan apes by similar suspensions of membranes of the 15th passage.

The naked-eye and microscopic changes produced in the chorioallantoic membranes are described. In all essential these appear to correspond to those described by SKORRIT *et al.* who in 1936 were the first to employ embryo chicks for cultivating the virus.

Round and elliptical inclusion bodies found in the mesenchyma cell of the infected membrane are described and illustrated. Their nature is regarded as doubtful.

John W. D. Megaw

BARLOVATZ, A. Fièvre rouge congolaise et mononucléose [The Red Fever of the Congo and Mononucleosis] *Ann Soc Belge de Méd Trop* 1948, Sept 31, v 28, No 3, 315-43

The author gives a clinical description of an epidemic of a short fever which occurred during the first half of 1948 at Yangambi on the Congo River 100 kilometres down-stream from Stanleyville

There were 30 cases among the European population and it is stated that sometimes as many as 50 per cent of the Europeans in certain localities of the Belgian Congo are attacked by the disease

The disease is described as a fever with rapid onset, lasting a few days, and associated with a scarlatiniform, rarely morbilliform, rash. A variable degree of enlargement of the lymphatic glands occurs. Asthenia and rheumatic pains often persist for a long time after defervescence

At the onset leucocytosis was usual, but in three of the nine cases in which the results of repeated blood counts are given the total leucocyte count fell rapidly, in one case to 2,000, in another to 2,100, and in the third to 3,300 per cmm. In the later stages there was often a pronounced lymphocytosis or monocytosis. The Paul-Bunnell reaction (agglutination of sheep erythrocytes) was positive in some cases, and the author regarded the disease as being clinically related to the "infectious mononucleoses". He admits, however, that it is not easy to differentiate the disease from dengue, the only points mentioned being that the saddle-back temperature curve which occurs in typical dengue was hardly ever seen in the Yangambi epidemic, and that the rash appeared rather earlier than would be expected in dengue

[Apparently the name *fièvre rouge congolaise* has been applied to several kinds of short fever, and in most cases the term P U O (pyrexia of uncertain origin) would be more appropriate]

RABIES

WRIGHT J T & HABEL, K. A Comparison of Antigenicity and certain Biological Characteristics of 6 Substrains of Pasteur Fixed Rabies Virus. *J Immunology* 1948, Dec, v 60, No 4, 503-15, 2 figs [22 refs]

In a previous article [this *Bulletin*, 1948, v 45, 478] it was shown by the authors that different substrains of the original Pasteur fixed virus varied in their ability as challenge virus to produce rabies in mice equally immunized by any given vaccine, including a vaccine prepared from the homologous virus. This ability to break down a given amount of immunity—designated as the relative "invasiveness" of the viral substrains—appeared to be unrelated to the degree and breadth of the antigenicity of the substrain used as a vaccine and to its ability to produce rabies in non-immunized animals. [The substrains in question had been carried in different laboratories over a period of years by different workers using different intracerebral passage techniques]

If as the authors believed this ability to break down immunity by an intracerebral challenge was an essential characteristic of the viral substrain, then it should be capable of demonstration by immunological techniques, other than the intracerebral cross-immunity type of test

partial kills. Barium carbonate gave good but not complete kills at concentrations up to 50%, while strychnine sulfate killed few rats in the range tested.

"The amounts of unpoisoned cornmeal consumed on 2 successive nights, by male and female wild Norway rat in various weight groups were determined. The addition of very poison except thallium sulfate to the cornmeal caused a considerable reduction in intake owing thereto recognition of the poison or to a rapid onset of toxic effects."

CHOLERA

SNOLSKA, A. T. Cholera Epidemic in Egypt (1947). A Preliminary Report. *Bull. World Health Organization* 1948, 1 No. 2 353-81 1 map & 1 chart.

This preliminary report on the cholera epidemic in Egypt in 1947 summarizes the main features of the outbreak and the measures undertaken for its control. Egypt which had been infected during five out of six of the great pandemics of the 19th century and had suffered severely had been free from the disease for 45 years when cases were detected in September 1947 at the village of El Korein in the Delta, without any warning having been given of an approaching risk, or any indication obtained from mortality statistics of a rise in incidence of epidemic disease. Immediately cholera was suspected El Korein was cordoned off to prevent entry and exit in the hope of limiting the spread of the disease but almost at once cases were detected at Mostorod in the Bahiyah Province and at other points in the area.

To cope with the risk of an epidemic special administrative and sanitary measures were immediately instituted, powers being taken by the promulgation of special decree-laws to restrict movements, to regulate supplies and to enforce sanitary and other precautions which might assist in limiting the spread of the disease. Control of traffic by rail road and river was introduced and movement from infected to uninfected area was prohibited except in the case

Daily cases and deaths in the Delta epidemic 1947
Reproduced from the Bulletin of the World Health Organization

of persons in possession of valid certificates of inoculation with cholera vaccine. Inoculation of the crews of river craft and ferries was undertaken from the beginning of the outbreak. In spite of these precautions, cholera spread to all provinces of Lower Egypt and, although rail traffic from Lower Egypt was entirely suspended for six days to allow of the inoculation of travellers, Upper Egypt also eventually became infected.

The details of spread, in chronological order, to different parts of the country, have been published in successive issues of the Weekly Epidemiological Record of the W H O [the subject has been fully reviewed in this *Bulletin*]. From the commencement of the outbreak on 22nd September to its termination at the end of November, 1947, with a few subsequent dropping cases, the total incidence recorded was 20,804 cases with 10,277 deaths giving a case mortality of about 50 per cent. The rise and fall of the epidemic is shown in the chart.

The weekly incidence by Provinces and Governorates is shown in a table (II), the highest number of cases being in the Provinces of Beheira, Gharbiya, Minufiya, Dakahlia, Sharqiya and Kalyubia in Lower Egypt. Incidence in the towns, Cairo, Alexandria, Port Said and Suez, was low.

A very brief summary is given of the measures taken. These include isolation of patients, inoculation of contacts at the beginning of the epidemic, followed by mass inoculation of the entire population, protection of water supplies and provision of temporary supplies, measures to prevent infection from food and drink, improvements in general sanitation, and an anti-fly campaign.

To carry out the various measures applied in control and in care of the sick, a special organization was built up, the scheme for which is summarized in Table VI of the report. Members of the senior staff of the central administration were appointed to supervise the operations in each area and to arrange for staff equipment and supplies. A very large staff was placed on cholera duty, the total eventually including 930 doctors, 479 sanitary inspectors and 820 nurses.

For the early detection of cases of cholera, "flying squads" were formed to search villages and to carry out disinfection, protection of water intakes and other immediate measures. When the epidemic abated, alert measures were instituted for the purpose of detecting any persisting infection. All cases of vomiting and diarrhoea were dealt with as cholera until a bacteriological examination gave a negative result. Enquiries on all deaths were made by a medical officer of health or a sanitary inspector and swabs taken from the rectum for cultures. Out of 13,739 swabs examined between 16th December, 1947, and 12th January, 1948, positive findings were made in 43. A continuous search for carriers was undertaken.

Short notes on some of the measures taken and on the observations made are given in the report.

Protection of water supplies—The dose of chlorine added to public water supplies was increased. Pipe lines were extended to suburbs of towns and cities and new sanitary pumps installed at villages which had not previously had pumped supplies. All Abyssinian wells (drawing water from a few feet below the surface) and open wells, were closed. Where the source of supply was from canals, sites were selected at which, only, water would be drawn and the raw water was disinfected by the addition of chlorine solution or bleaching powder.

Isolation and discharge of cases and contacts—At first the patients were isolated in the nearest infectious diseases hospital, but as their numbers increased practically all hospitals and health centres, with the exception of one in each province which was kept for emergencies, were temporarily converted for use as cholera hospitals. Additional accommodation was later provided in tents, huts, schools or other buildings. House contacts were isolated in any available buildings and when isolation was not possible surveillance was carried out.

the incubation period. The practice adopted in regard to discharge of convalescents was to carry out a bacteriological examination of the stools on the 5th day of convalescence and again three days later. If both specimens were negative the patient was discharged usually about the 19th to 24th day from the onset of the attack. If a positive result was reported three consecutive negative samples at intervals of three days, were required before discharge. In the case of contacts, if two samples taken on the 2nd and 4th days of isolation were negative discharge was permitted. If one sample was positive three consecutive negatives, as in the case of convalescents were necessary. A five-day course of sulphaguanidine was given to both convalescent and contacts while under observation and repeated if the vibrio could still be isolated.

Duration of the carrier state—Observations were made on the period of persistence of the vibrio in the stools of 463 convalescents in four hospitals. The findings are shown in Table V of the report. The minimum and maximum periods from the beginning of the attack at which the vibrio was isolated are stated to be respectively 7 and 4 days. (A considerable difference is shown in the table on the findings in the four hospitals. In Cairo and Alexandria respectively only 14 per cent. and 5.2 per cent. were positive after the 15th day while in Zagazig and Tanta the figures were 31 per cent. and 76.7 per cent. respectively.)

Positive cultures were obtained from 288 out of 13,702 contacts examined, giving a rate of 2.1 per cent. Of these 85 developed the disease i.e., 0.6 per cent. of total number of contacts. Table VIII of the report shows the duration of excretion of the vibrio by contacts. The majority were negative after 5 days and 83.6 per cent. were negative after 10 days. The maximum period observed was 19 days.

Observations made on the effect of sulphaguanidine and sulphacetamide on the persistence of the vibrio (Table VI) favour the use of the former drug.

The bacteriological work carried out during the epidemic involved the examination of 119,079 specimens.

*Survival of *V. cholerae**—Investigations were carried out on the periods of survival of *V. cholerae* on different foods and material contaminated in one set of experiments with faecal material and with cultures in another. The results are summarized in a table. The food-stuffs tested were onion, garlic, orange, lemon, grapes, dates, lentils, rice, sugar and bread. The other articles were coins, postage stamps, bank notes and cloth. The vibrio was not recovered later than the third day on any of the food-stuffs or materials when fresh stool material was used. Survival in acid fruit such as lemons and oranges was a matter of a few hours only. The findings are tabulated.

Inoculation—Inoculation of the whole population with cholera vaccine was undertaken. At the outset of the epidemic only a small stock required for the inoculation of pilgrims was in hand and it became necessary to supplement local manufacture by obtaining supplies urgently from other countries. Over 5 million ml were received as donations and 10 million ml on payment. Later the production at the Vaccine and Serum Institute in Cairo was stepped up from 40,000 ml daily to 400,000 ml to meet the requirements. The dose employed in the mass inoculation campaign was 1 ml containing 800 million vibrios. Staff working on cholera were given two doses, 0.5 ml followed by 1.0 ml one week later. A complete re-inoculation of the population was undertaken commencing on 15th February, 1949 as a precaution against recurrence of cholera.

In discussing the evidence on the value of inoculation the opinion is expressed that "While it is difficult to believe that inoculation alone accounted for the complete suppression of the epidemic there is no doubt that it was of great importance in modifying the general trend of the outbreak and in reducing

incidence and mortality. The findings suggest that the epidemic of cholera was finally ended by large-scale vaccination." A comparison is made between the incidence and the fatality rate in the 1947 epidemic as compared with that of 1902, when the population was only half that of the present time. The gross morbidity rate is estimated to have been four times less in the recent outbreak and the mortality rate seven times less than in 1902, when no vaccination was undertaken. The figures of eight different fever hospitals show that 18.7 per cent of the cases were in inoculated persons, 81.1 per cent in the uninoculated, the case mortalities in the two groups being 26.5 per cent and 42.9 per cent, respectively.

Anti-fly campaign.—In view of the possible risk of carriage of infection by flies a vigorous anti-fly campaign was undertaken in which the Insect Eradication Section and the Malaria Section of the Ministry of Public Health were employed. Aircraft were used for the purpose, "fogging" being carried out with a 20 per cent solution of DDT in Velsicol, and "spraying" with a 10 per cent solution in kerosene. A 7 per cent solution of DDT in Malariol was also used for ground fogging by discharge from the exhaust of a jeep. Hand-guns and mechanical pumps were used inside houses. A special evaluation of the results was undertaken by the staff of the Insect Eradication Section and a general decrease in fly population is claimed in treated villages as compared with controls. A separate report on the findings will be published.

Quarantine restrictions.—Under the heading "Cholera Hysteria," the author refers to the restrictive measures applied by certain countries against the risk of the introduction of cholera infection, which far exceeded the provisions of the International Sanitary Conventions. These included, in some cases, the complete closure of frontiers against passengers and goods, and even mail, from Egypt. One country prohibited the importation of food-stuffs, not only from Egypt, but also from eight countries "threatened" with cholera. "Other countries prohibited not only food-stuffs, but also Egyptian cotton, forgetting the fact that they had been importing for years jute from Bengal and rice from China and Indo-China, the main endemic and epidemic centres of cholera, without any evil consequence." "International control as provided for in the conventions, ought not to be set at naught and disregarded on the principle of each country for itself." Comment is made on the importance of developing a long-term policy of sanitary improvement in the known endemic areas of cholera, for the purpose of reducing the risk of spread or even eliminating infection altogether.

In concluding the report, acknowledgment is made of the generous help given to Egypt by States and private organizations during the epidemic and to the assistance rendered by the World Health Organization.

This preliminary report will form a useful background to more extended publication on the various aspects of cholera as seen in Egypt and on the observations made.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

SPINGARN, C. L. & EDELMAN, M. H. The Use of Streptomycin in the Cultivation of *Endameba histolytica* from Stools. *Amer J Trop Med* 1948, Nov, v 28, No 6, 825-9.

It is difficult to grow *Entamoeba histolytica* successfully from stools containing cysts alone. If streptomycin is added to the culture medium much better results can be obtained, even from stools a week old. Three drops of faecal suspension are added to the mixture of horse-serum and saline covering the

solid slope [this *Bulletin* 1948 v. 45:428]. Streptomycin in varying concentrations (1 to 10 mgm. per cc.) is also added: there is no optimum dose, because each strain behaves differently.

Control tubes without the antibiotic were set up and inoculated. Positive cultures were obtained in 8 per cent. of the controls and in 73 per cent. of the streptomycin tubes. The growth of *Blastocystis* and of bacteria was much inhibited in the latter. Trophozoites of the amoeba were usually abundant and subculture was easy. Excystation occurred within 48 hours at 37°C. but might be delayed for nine days.

The employment of a standardized technique would prove useful in the numerous cases where amoebiasis is suspected but the diagnosis is not completely established.

CHU, C. H., T. C. W. H., CHU, H. T. & LI, C. H. *Endamoeba histolytica* and other intestinal protozoa in Szechwan. A Preliminary Report. *Chung Hwa Yeh J. Chemist* Edition 1945 Apr. v. 63, No. 3:134-8. [13 refs.]

THOMPSON, M. Le forme a tipo setticemiche dell'amebia L. (Amoebiasis with Septicaemic Type of Symptoms.) *Boll. S. Italiani di Tripolitania* 1943, July-Dec. v. 6 No. 3/4:17-21. [11 refs.] English summary (8 lines)

Many patients with *E. histolytica* appear to enjoy perfect health: others may show symptoms who have never suffered from dysentery but become alarmingly ill with symptoms pointing to involvement of other organ: for example liver, lungs, brain. Some cases resemble typhoid, or malaria, or undulant fever or appendicitis. In others there may be no localizing symptoms but fever remittent or intermittent with sweats, shiverings, slight enlargement of the spleen. Widal negative, leucocytes not increased (8,000-8,100 per cmm).

Three such cases are detailed. For a time they were very puzzling but examination revealed that the patients were passing *E. histolytica* or its cysts or both. Treatment with emetine was started. Improvement was seen in one patient a lad of 17 years after the first injection: the other lost their fever in 4 days and progressed uninterruptedly to recovery. The author postulates that the amoebae may settle in some focus without producing symptoms, or that there may be temporarily at least, immunity to their presence in the intestine: that this breaks down and a septicæmic condition—an amoebiæmia—be set up.

COXON, R. V. Some Observations on Amoebic Dysentery. *J. Roy. Army Med. Corps.* 1948 Dec. 91 No. 6:243-50. 17 refs.

The material for this paper was collected in India during 1943 and 1944. All cases were considered primary and all in the control series had lesions demonstrable sigmoidoscopically.

Emetine (0.065 gm.) was administered by deep subcutaneous injection: emetine-bismuth-iodide was given orally—a powder derived from crushing a tablet preparation, the daily dose (0.2 gm.) being taken in the evening. In the majority of cases the first dose induced marked degree of nausea which was taken to imply that it was being satisfactorily absorbed. For quinine retention enemata 250 ml. of a 2.5 per cent. (w/v) solution in water were used. The enema was preceded by a wash-out with 2.0 per cent. aqueous sodium bicarbonate solution with the patient lying on the left side and afterward adopting the knee-elbow position. A series of 9 cases receiving no special treatment as retention enemata of saline were retained as control.

Amibiarsen (Martindale, 1941) was given by mouth in form of tablets, the dose being 0.25 gm morning and evening. Oral quinoxyl was in aqueous solution, two doses, each containing 0.25 gm, were given daily.

Test of Cure—Specimens of 6 stools passed at intervals of not less than twenty-four hours were examined for trophozoites and cysts of *E. histolytica*. Sigmoidoscopy being negative the patient was transferred to the Convalescent Depot for 3 weeks where he lived on normal Army rations. At the conclusion three further specimens of faeces were examined and another sigmoidoscopy was made.

A case was recorded as a "success" if, at the conclusion of this period, no evidence of recurrence had been obtained.

The schedules of treatment are shown in a table and are divided into 5 groups.

1 Emetine, 0.065 gm daily, 1st to 6th day, EBI, 0.2 gm daily, 7th to 12th day and 20th to 25th day, quinoxyl rectally, 5th to 14th days, amibiarsen, 0.25 gm twice daily, 13th to 25th day.

2 EBI 0.2 gm daily and quinoxyl rectally, 1st to 10th day, quinoxyl 0.25 gm twice daily, for one month.

3 Emetine 0.065 gm daily, 1st to 6th day and 10th to 15th day, amibiarsen, 0.25 gm twice daily, 7th to 16th day.

4 EBI 0.2 gm daily, 1st to 11th day.

5 (Control) Distilled water, 1 ml, 1st to 6th day, sodium bicarbonate 0.5 gm, 7th to 12th day and 20th to 24th day, rectal saline, 5th to 14th day, glucose, 1 gm twice daily, 13th to 25th day.

The successes for each of the first four groups are shown respectively as 91.7, 72.7, 92.3 and 80 per cent (average, 84.8) for the control group, the successes are shown as 22.3 per cent.

Concomitant bacillary infection was discovered in nine cases and sulpha-guanidine was considered to be indicated only when frequency of defaecation was exhausting or there was severe tenesmus. On several occasions amoebae were seen moving among cells of a typical "bacillary exudate".

In the control series of 6 cases receiving no specific treatment, the ulcers which had been visualized through the sigmoidoscope disappeared within periods varying from ten to twenty-four days.

It is concluded that reasonably satisfactory results could be achieved by either oral EBI or parenteral emetine combined with an organic arsenical, but no appreciable improvement resulted from the addition of quinoxyl retention enemata while sigmoidoscopic observation of control cases showed healing of amoebic ulcers in absence of specific medication. *P. Manson-Bahr*

GIMBLE, A. I., DAVISON, C. & SMITH, P. K. *Studies on the Toxicity, Distribution and Excretion of Emetine*. *J. Pharm. & Exper. Therap.* 1948, Dec., v 94, No 4, 431-8, 4 figs. [10 refs.]

In this investigation on the toxicity and metabolism of emetine in animals, two methods were used for estimation. The first, described by BRODIE *et al.* [this *Bulletin*, 1947, v 44, 793] in which methyl orange is the reagent can be used generally for organic bases but is not specific. By washing the ethylene dichloride tissue extract with phosphate buffer at pH 7.5 the method gave greater specificity and increased accuracy. Before extraction, the protein to which emetine is firmly bound was precipitated with trichloroacetic acid. The colour developed was read in a spectrophotometer at 540 m μ and then compared with standards. In a second method, use was made of the ultraviolet absorption curve of emetine as determined in a Beckman spectrophotometer. Details of the procedure should be consulted in the original.

Acute toxicity was determined in rat and mice by intraperitoneal injection. The LD₅₀ in mice was 62 mgm. per kilo. and in rats 17 mgm. per kilo. After administration of 40 mgm. emetine per kilo. to groups of mice the drug content of the whole animal was determined at intervals up to 35 days. The amount present decreased till the 8th day when approximately 35 per cent of the administered dose remained in the body and was approximately the same in amount until the 35th day indicating that the drug was slowly disposed of. These observations are in agreement with the fact that repeated small doses prove as toxic to animals as a single large dose. When the above dose was doubled the residual drug in the body was the same as above so that above a certain storage level emetine appears to be excreted or destroyed. Distribution in the different tissues of rat and dog showed that most was stored in the liver and may explain the drug's effectiveness in amoebic abscess of that organ. Smaller amounts were present in kidney spleen lung brain heart muscle and blood in that order. The small amount present in heart was surprising since it exert marked toxic effect on this organ. Urinary excretion alone was studied in the same animals and one human patient. Only traces of emetine could be found in a 24-hour sample and the drug was evidently not excreted to an appreciable extent by that route.

I. RICKARDS, A. G. The Treatment of Amoebiasis with "Diodoquin." *J. Trop. Med. & Hyg.* 1949 Feb., v 52, No. 2, 33-8. (14 refs.)

II. *J. Trop. Med. & Hyg.* 1949 Feb., v 52, No. 2, 23-4. The Cyst Passer again.

I. This survey includes the treatment of 177 consecutive cases of amoebiasis of all grades treated with diodoquin. In all ambulant treatment was adopted. The post therapeutic supervision proved difficult as the men were demobilized a month after therapy was finished and all faeces examination thereafter had to be undertaken on specimens sent by post.

The criteria of cure consisted in the remission of symptoms and examination of not less than 8 faecal specimens within a period of not less than three months after cessation of therapy.

The series was grouped into —

Group I Asymptomatic.

Group II Asymptomatic with visible lesions on sigmoidoscopy.

Group III Symptomatic with no bowel lesions on sigmoidoscopy.

Group IV Symptomatic with bowel lesions on sigmoidoscopy.

171 fell into the first three groups. 98 were in Group I, 7 in Group II and 18 in Group III.

As the first three belong to the non-dysenteric type they may be considered together. Of these 119 were classed as cures, 16 as failures and 15 as having insufficient data.

The highest relapse rate (25 per cent) occurred among those treated by an eight-day course of diodoquin. This rate was reduced to 10 per cent among those receiving a fourteen-day course and to nil among those receiving a twenty-one-day course of therapy. Patients in Group IV were most unsatisfactory. All cases came from India and there was only one cure. In three diodoquin treatment was combined with E.B.I. Regarding toxicity the high sodium content of diodoquin precludes a greater potential danger of toxicity than does iodoform.

In the present series of 177 cases only 18 instances of untoward effect after administration of the drug were encountered. Pruritus and was the most prominent but was never a serious contraindication. Headache was not a prominent feature.

The disappearance of *Entamoeba histolytica* from the faeces showed a marked constancy in the first three groups and in only two could cysts be found five days after therapy was begun, but the interval of disappearance was longer in the last group of cases. *E. coli* and *I. bütschlii* were quickly eradicated, but *Giardia intestinalis* and *Endolimax nana* were resistant.

The usual dosage in the first three groups was 9 tablets (28.8 grams) *per diem*. From the results of treatment among the first three groups it is clear that there is a marked reduction in the relapse rate in those men treated for a longer period. It appears that less than twenty days treatment must be considered inadequate.

The maximum dosage was 1,123.2 grams (351 tablets) given within thirty-five days and no untoward reactions were produced.

The response to treatment was more marked in the acute forms of the disease when complete relief from symptoms was often obtained. One patient gained 7½ lb in weight within fifteen days and all the remaining cases showed such an initial dramatic clinical improvement. Sigmoidoscopic appearances ran a parallel course.

The earlier American reports of the efficacy of diodoquin have not been confirmed, but there is no doubt that it is a useful addition to the list of amoebicidal drugs and the main indication lies in the treatment of the symptomless cyst-passer on account of its low toxicity.

It should, however, never be used alone in the treatment of the disease, but is of real value when used in combination with emetine compounds. In an editorial commenting on this paper and a previous one by the same author [this *Bulletin*, 1949, 46, 361], reference is made to the problem of the cyst-passer and the significance of asymptomatic ex-servicemen returning to the community. The greater incidence and far greater morbidity from *E. histolytica* infection in this series among men returning from the India-Burma area as compared with those from the Mediterranean is discussed and it is suggested that some local factor is involved and that, perhaps, such a factor is absent altogether in temperate countries.

LAVIER, CROSNIER & MERLE. Traitement de l'amibiase par la conessine [Treatment of Amoebiasis with Conessine]. *Rev. Paludisme et Med. Trop.* 1949 Jan 15, 7 No 56 1-8.

The authors and other French workers, have already recorded satisfactory results in the treatment of amoebiasis with conessine [this *Bulletin* 1948, 45 905 and 1086]. With further experience of it they confirm their view that conessine is the equal of emetine not only in the treatment of intestinal amoebiasis but in that of acute amoebic hepatitis. The drug is well tolerated by young patients and with habituation by others, though sedation is necessary in some cases.

LARSH, J. E. Jr & CHAFFEE, E. F. The Effectiveness of Carbarsone in rendering Young Mice Free of Intestinal Protozoa. *Science* 1948, Dec 24 725.

The common laboratory rodents are naturally infected with amoebae and attention has been drawn to this fact in connexion with the use of rats as experimental hosts for *E. histolytica* by FLITON & JOYNER [this *Bulletin* 1948, 45 430]. The present authors have attempted to free mice, kept under controlled conditions from intestinal protozoa by means of carbarsone. Groups of animals which received 50 to 300 mgm of the drug daily per kilo by mouth

for 10 days were not rendered protozoa free by this treatment. Doses up to 1,500 mgm. per kilo. proved effective in reducing their numbers but failed to eradicate them.

NEAL, R. A. *Entamoeba muris*: a Complicating Factor in the Experimental Infection of Rats with *E. histolytica* [Correspondence] *Nature* 1949 Jan. 13 99-100 2 figs.

As recently pointed out by FULTON & JOYNER [this *Bullet* n 1949, v 45 430] the presence of natural amoebic infections in rodent used for experimental infection with *E. histolytica* may give rise to difficulty in interpretation of the results obtained. The present author indicates that infection with *E. muris* may be avoided by selection and care in maintenance of animals used. The effect of emetine and carbanone on young rats experimentally infected with *E. muris* through giving mature cysts in food, has been determined. Treatment by the drug-diet method was begun immediately after giving the infection and lasted for 6 days. The drug proved ineffective against *E. muris* as was found by HEGNER & ESKRIDGE (*J. Parasitology* 1939, v 22 408). Some morphological descriptions of the rat parasite are added.

RELAPSING FEVER AND OTHER SPIROCHAETOSIS

GAMBLES, R. M. & COGHILL, V. F. Relapsing Fever in Cyprus. I. A. *J. of Med. & Parasit.* 1948 Dec., v 4, No. 74 288-303 1 map. 35 refs.

Relapsing fever has probably been endemic in Cyprus for many years but was not diagnosed until 1939 when spirochaetes were found in the blood of two gold miners suffering from fever. Between 1941 and 1943 98 soldiers contracted the disease and cases also occurred among the civilian population. The origin of some of these cases was discovered by WOOD & DIXON (this *Bullet.* 1946

43-44) they noted that the soldiers had been using caves or dungeons containing the tick *Ornithodoros tholozani*. The present authors extended these observations and discovered that the disease was widespread in Cyprus. Clinically the cases did not resemble the house-borne form and most of the patients were later proved to have been in contact with ticks. One of such ticks was sent to ADLER who was able to prove that it was infected with spirochaetes. Other transmission experiments with ticks were negative.

O. tholozani was found in nine different sites in Cyprus. Never found in human habitations the ticks occupied caves, rock shelters and once a ruined church. The ticks live in the dry earth or sand on the floor of the caves in rat holes or even in the earth at the base of a cliff below the cave. The ticks appear to flourish particularly where the floor is inches deep in guano. Infection takes place not only in people sheltering or sleeping in the caves but also in those merely visiting and crawling about in them. The prolegs of ticks attach to it, movements, attacking the legs and ankles and remaining in the clothing after engorgement. The tick probably feed on rodent man is only an accidental host. The only rodent reservoir of spirochaetes was investigated by examining the blood of 10 black rats and one spiny mouse from places known to be infected with the disease. The brains of nine of the rats were also inoculated into guinea-pigs. All the results were negative. Ticks were kept alive unfed for a long as 490 days.

P. C. C. Graham

ASHBEL R. Notes on *Spirochaeta persica* from Palestine and *Spirochaetes* of Relapsing Fever from the Western Desert (Tobruk Area) [Correspondence] *Trans Roy Soc Trop Med & Hyg* 1949, Jan, v 42, No 4, 409-10

A summary of observations on thirteen strains of spirochaetes isolated from twelve patients and one tick (*Ornithodoros tholozani*) at Tobruk, and a comparison with strains of *Spirochaeta persica* from Palestine. The cases of relapsing fever occurred among soldiers in the Western Desert and the strains were supplied by Col. Boyd and Lt. Col. Little G.H.Q., Middle East Command.

Guinea-pigs were found to be highly susceptible to 11 of the Tobruk strains but resistant to two of them. After intraperitoneal injection the incubation period in guinea-pigs varied from 2 to 10 days, and there was no uniformity in the course of the infection. Some of the animals showed a heavy infection lasting about a fortnight without any relapse, while others had 3 and 4 relapses in the space of 2 or 3 weeks, and one individual even 5 relapses.

In the case of the Palestine strains an animal can be considered to have recovered when its blood remains negative for one month, but Tobruk strains can still be transmitted by the inoculation of heart blood 10 months after the disappearance of spirochaetes in thick drop examinations. In both strains the brain remains infective after the blood has become negative. In the case of the Palestine strains the brain has been shown to be infected 20 months longer than the blood in rats, and more than a year longer in guinea-pigs. The total period of brain infectivity with Tobruk spirochaetes has not yet been ascertained.

Guinea-pigs which have recovered from infection with Palestine strains remain immune to the same strains. In the case of the Tobruk strains some animals develop specific immunity, while others do not, and in the latter cases a second infection with the same strain produces an infection equally as heavy as the first. On the contrary, an animal infected with the Palestine strain, if inoculated with a new strain, develops an attack less severe than the previous one. It was noticed in Tobruk strains that the longer the incubation period in an animal, the more severely does it become infected, and some of these animals died with haemorrhages in the lungs, liver, peritoneum and brain.

Ornithodoros tholozani was shown to be capable of transmitting the Tobruk strains by bite. The contents of lice fed on monkeys infected with Tobruk strains remained infective to guinea-pigs for a maximum period of 48 hours.

E Hindle

HEISCH, R. B. The Human Louse in Transmission of *T. duttoni* in Nature. *Brit Med J* 1949, Jan 1, 17

It had been previously shown [this *Bulletin*, 1948, v 45, 603] that the human louse could act as a vector of *Treponema duttoni* in the laboratory. This organism is normally carried by *Ornithodoros* ticks, now the author has shown that it can develop in lice recovered from patients suffering from the *duttoni* form of relapsing fever.

Lice were collected from the clothes of patients, they were kept for periods up to three days and were then inoculated into susceptible animals. The animals became infected with a spirochaete which showed the typical characters of *T. duttoni*. It seems probable that the louse may therefore be a natural vector of the disease, though why epidemics of louse-borne *T. duttoni* do not occur remains a mystery.

YANG R. Y. & TU, Sou-chao. Treatment of Relapsing Fever at the Chengtu General Hospital. *Chinese Med J* 1948, Aug, v 66 No 8 426-30

1. The results of treatment of 79 proved cases of relapsing fever in the Chengtu General Hospital from 1942 to 1944 were presented

2. Thirty-eight cases treated with arsenic preparation 3-4 days after the crisis of the first attack showed no relapse after 12-20 days observation following injection except one case treated with mapharsen.

3. Of 40 cases treated before crisis, relapse occurred in 7 with one death.

4. Phenarsine hydrochloride was found to be as effective as neoarsphenamine but caused more reaction.

YAWS

HACKETT C. J. The Bone Lesions of Yaws in Uganda. A Clinical and Radiological Study (Thesis presented to the University of London for the Ph.D. degree in the Faculty of Medicine November 1947) Typewritten MSS 262 pp 1 map 2 graphs & 133 photographic figs. [43 refs.]

This work records an extensive radiological and clinical study of bone lesions in yaws carried out from 1937-40 while the author was holding a Senior Fellowship in Tropical Medicine of the Medical Research Council. Two visits were made to the Lango district of Uganda. During the first visit 940 cases of yaws with bone lesions were studied and 230 patients were re-examined during the second visit a year later. The period of observation of individual patient ranged from 6 to 18 months, and some 3,000 X-ray and 5,000 clinical photographs were made.

The Lango area just north of the equator is low undulating savanna country interspersed with swamps. It has an average rainfall of about 57 inches falling in two periods with maxima in May and August. The Lango tribe was pastoral but is becoming agricultural. The diet is largely vegetarian and probably poor in animal protein and fat. Infants are breast fed for one to two years. Young children are usually naked but adults wear simple clothes.

That the bone lesions described in this work were indeed due to yaws seems beyond question for the following reasons. The majority of the patients had generalized yaws lesions or had a history of such lesions. The bone changes formed a connected whole such as may be expected from a single aetiological agent and they resolved after treatment with neoarsphenamine. Syphilis appeared to be so rare that it could be excluded as a cause of the widespread bone lesions and for the purpose of this study yaws and syphilis are regarded as two different diseases. In Lango yaws is common (among the 14,000 yearly annual out patient 30 per cent. show evidence of yaws) and typical syphilis is rare whereas the opposite obtained at Masaka. The nature and sites of the lesions excluded tuberculosis or leprosy as the specific cause of the bone changes. Nutritional deficiencies may predispose yaws patients to the development of bone lesions but there was no evidence that such deficiencies in themselves accounted for the lesion.

Classification of yaws

Secondary lesions resemble the initial.

Generalized secondary lesions have a granular appearance and pirochaetes are readily demonstrable in serum from the lesions. These lesions are never destructive and leave insignificant scars on healing.

Later destructive ulceration develops which on healing leaves thin shiny deeply pigmented, atrophic scars. Lesions of this type are never present at the same time as secondary lesions nor do secondary lesions develop into them. These are tertiary lesions and pirochaetes are rarely found in them.

Latent secondary cases are those without skin lesions but whose bone lesions resemble those usually found with secondary lesions. Sometimes typical secondary skin lesions develop later.

Similarly latent tertiary cases are those without skin lesions but whose bone lesions resemble those of tertiary cases

Secondary lesions cease to relapse within a few years after infection. Tertiary lesions develop some years after infection and follow a symptom-free period. At any stage the disease may become inactive.

Bone lesions in the various stages of yaws

Secondary cases—Among 169 secondary cases (167 with skin lesions and 2 in the "pre-secondary stage") 20 per cent were under 2 years of age and 70 per cent below 5 years of age, 108 patients complained of bone pains, often nocturnal, 123 had thickening of bones with tenderness, 100 had the initial lesion or its scar, all had some type of skin lesion. From examinations of the patients 6 to 18 months later, it appeared that active bone lesions were nearly twice as frequent in patients with relapsed skin lesions as in those with resolved skin lesions. Younger patients suffered relapses of skin lesions more frequently than older ones. It appeared that the younger the patient, the shorter the duration of the yaws, and the less numerous the neo-arsphenamine or bismuth injections, the greater was the tendency of the skin lesions to relapse.

The majority of bone lesions commenced during the first or subsequent generalized skin eruptions. All active bone lesions tended to resolve spontaneously after a few weeks or months, but treatment hastened healing. No ulceration of bone lesions through skin or spontaneous fracture was seen.

The radiographic appearances indicated active changes (rarefactions, periosteal deposits), and inactive changes (cortical thickening and bony expansion, sabre-tibia), combinations of these changes occurred. Sabre-tibia was probably due to periosteal deposits which had become organized on to the anterior surface of the cortex and increased its convexity; there was no evidence that yaws played an important part in producing bowing of the tibial shaft.

Of the bones radiographed the ulna was probably most frequently involved, next in frequency were the hand bones, tibia and fibula, and lastly the foot bones and radius. In the hands and feet usually many bones were affected but the terminal phalanges, carpus and tarsus were unchanged. Apart from gonorrhea, no clinical evidence was found of involvement of the skull, ribs or vertebral column, and radiographically no changes were found in joints, although free fluid was occasionally present in the knee joints.

The periosteal deposits indicate active periostitis, and the cortical rarefactions a rarefying osteitis, cortical and periosteal rarefaction and periosteal deposits can be regarded as an osteoperiostitis. Cancellous tissue rarefaction which was occasionally observed in young children, probably indicates localized metaphyseal osteomyelitis.

There were 15 patients, 12 males and 3 females, with granulomatous plantar yaws: three with active bone lesions were under 8 years of age, while more of the other cases were over 15 years of age than under. Most had had yaws some years before and all complained of pains in the bones, or in the plantar lesions. Absence of radiological evidence of bone lesions in some patients with bone pain was probably due to the changes being insufficiently gross. Most of the patients showed bone changes that could well be attributed to previous secondary lesions, and the active bone lesions were comparable with those seen in secondary cases.

Latent Secondary Cases—There were 65 patients with no secondary yaws skin lesions but who were considered to be in a latent secondary stage. Of these, 18 had periosteal deposits only, 31 had cortical rarefactions and periosteal deposits, while of the remaining 16, 4 had cortical thickening and expansion,

3 organizing periosteal deposits, 4 inactive sabre-tibia, and 5 no bony abnormality. Fourteen of the first group of 18 patients were under 10 years of age and most had had yaws a year or more previously. Pain in thickened bones was the most frequent complaint. Many of the bones showed the results of earlier secondary yaws lesions, i.e. thickening and expansion and added to these were periosteal deposits similar to those seen in other secondary cases. One case when seen later had developed a further eruption of secondary skin yaws.

Twenty three of the second group of 31 patients were 10 years of age or under and in most cases yaws had been contracted some years previously. All complained of bone pain and had tender bony thickenings. The cortical rarefaction and periosteal deposits observed and the changes that occurred on resolution were comparable with those in the secondary cases although minor differences were observed and bony expansion and cortical thickening were more frequent.

All patients of the third group of 18 had yaws a year or more previously and most of them complained of bone pain. Their ages ranged from 4 to 20 years but 13 were between 8 and 18 years of age. In 5 cases no bony changes were present and 4 had sabre-tibiae. The changes in the other cases were comparable with those seen in other secondary cases. One case 18 months after the first observation had secondary palmar and plantar yaws.

Tertiary Cases.—One hundred and nineteen patients were regarded as having tertiary lesions. Radiologically they fell into 4 groups: 15 with small well-defined cortical rarefied foci, 48 with large well-defined cortical rarefied foci, 28 with ill-defined cortical foci and the remaining 30 patients.

Of the first group of 15 patients 9 were over 15 years of age and all had had yaws some years before. All complained of pain and in 7 the duration of the symptom was 9 months or over. Tender bony swellings or nodes were present in all patients together with small (1-3 mm diameter) cortical rarefactions. In two cases tertiary yaws skin ulceration was present and in one ulceration through the skin from a bone lesion occurred.

Of the second group of 48 patients 17 were 10 years of age or under while 19 were over 15 years. All had had yaws in most cases several years previously and all complained of pain, mainly in thickened and tender bones. In 18 patients the duration of the complaint was 12 months or less and in 30 over one year. Nodes on the skull and tertiary yaws ulceration were present in some cases. The tibia, ulna and radius were most frequently affected. The radiographic appearances consisted of moderately well-defined rarefied foci (5 mm diam.) in localized or extensive cortical thickening and expansion. Probably the earliest changes were rarefied foci in the cortex. Periosteal deposit then appeared and became organized. In these deposits the foci extended or in them some other foci appeared. On resolution periosteal deposit and rarefied foci disappeared and the expansion and cortical thickening were reduced although usually some expansion and thickening remained. During the height of activity in some cases ulceration occurred from the bone lesion through the skin. In many patients seen several months to a year after the first observation the bone lesions had resolved but in some they had persisted, enlarged or more recent lesions had appeared. In many cases the tibiae were bowed but no increase in this deformity was observed during the period of observation. In one patient there were gross lesions of the hip joint and in a few there were rarefied areas in the epiphyses or metaphyses. A spontaneous fracture of long bones was observed.

Of the third group of 28 patients 17 were 10 years of age or under and 11 were over 15 years of age. All had had yaws in most cases for a number of years and all complained of pain usually in thickened and tender bones. In over half the cases the duration of the complaint was 6 months or less and in nearly a

third it was a year or more. Tertiary skin lesions were present in some cases. In the radiographs, large ill-defined foci of rarefaction were found in the cortex which was often thickened, the changes were localized rather than generalized. The evolution of the lesions resembled that of the cases with large well-defined rarefied foci. Ulceration of bone lesions was also observed. In many patients the tibiae were bowed, but no alteration in this was found during the period of observation. In two cases there were destructive lesions of the articular surfaces of the elbow and knee. In one case there was ankylosis of the elbow and in another spontaneous fractures occurred in the ulna.

In the remaining group of 30 patients, one was 7 years of age and 26 were over 15 years. All had had yaws some years previously and all complained of pain in bones or skin lesions, in a number tertiary skin lesions were also observed. In the radiographs a variety of changes were present, including rarefactions, periosteal deposits, cortical thickening and arthritis. In two patients with hydrarthrosis and in three with tertiary skin ulceration, no change was found in the bones.

The characteristics of tertiary lesions in the hand bones were the relatively few bones involved and the destruction that often occurred, carpal bones were sometimes involved. Sinus formation, spontaneous fracture, shortening and deformity often developed, and some lesions were of long duration. The changes in the bones of the foot resembled those of the hand but were probably less frequent. The tertiary lesions in the skull comprised gangosa and areas of rarefaction in the normal or thickened cortex of the outer table of the calvarium. The cortical rarefactions were associated with fluctuant swellings which might undergo absorption or ulceration.

In tertiary cases, the periosteal deposits may be regarded as evidence of periostitis, and the rarefactions indicate localized areas of osteitis. Bony expansion and cortical thickening result from periosteal activity depositing bone on the surface of the cortex. In brief the radiographic appearances indicate a focal destructive inflammatory reaction of the various tissues of bone. Some lesions were more diffuse and less destructive.

It was noted that non-yaws ulceration was not associated with rarefied foci in underlying bones, although periosteal deposits and cortical thickening might be present. Slightly bowed tibiae were found in some patients who probably had not had yaws.

Summarizing the radiographic findings, secondary cases showed focal rarefactions in the cortex, and periosteal deposits in which rarefactions also occurred. As resolution proceeded, the rarefactions usually cleared up before the periosteal deposits were absorbed or became organized on to the surface of the cortex. Although in many lesions the bones finally returned nearly to normal appearance, cortical thickening and bone expansion sometimes resulted. In the tibia such changes might lead to increased convexity of its anterior profile (sabre-tibia) although actual bowing of the tibia is probably due to some factor other than yaws, possibly nutritional. In secondary bone lesions and, to a less extent, in tertiary lesions, spontaneous resolution in a few months was the rule, but healing was hastened by specific therapy.

Secondary bone lesions were not destructive, but recurrence of activity was not infrequent after apparent resolution. The dactylitis of this stage involved many of the metacarpals and phalanges, but the distal phalanges, carpus and tarsus were not affected. Often many long bones were involved. Spontaneous fractures, lesions of the skull except goundou, ribs and joints and ulceration of bone lesions through the skin were not observed. No change resembling active rickets or syphilitic osteochondritis was found.

In tertiary cases the main changes were small (1-3 mm) and large (5-10 mm) well-defined rarefied foci, and ill-defined foci (10-20 mm), in the cortex which

might or might not be thickened. Lesions were more localized than those in secondary cases. The rarefied foci were single or multiple discrete or confluent localized or extensive. Periosteal deposits were often present and in some cases the rarefactions extended into these or involved the medullary trunks. On resolution the periosteal deposits were usually absorbed or became organized on to the cortex before the cortical rarefactions were filled in. Although in a few cases no gross alterations in the bone resulted often some thickening and expansion remained.

Tertiary bone lesions were more destructive and lasted longer than secondary bone lesions. They often ulcerated through the skin. The skull ribs, clavicles and epiphyses were affected. A few instances of involvement of joints and of spontaneous fractures especially of the phalanges were observed. The vertebral column was not radiographed and no clinical evidence of its involvement was found at any stage. In the hands and feet one or only few bones were affected and bones of the carpus and tarsus were involved in the tertiary stage.

The bone changes associated with tertiary yaws skin lesions or with chronic non-specific skin ulceration consisted of periosteal deposits and cortical thickening and never of rarefied foci of any form.

A comparison of bone lesions of syphilis with those of yaws shows the great similarity between them. The periosteal deposits and cancellous tissue rarefactions of secondary yaws resemble changes of congenital and secondary acquired syphilis. Rarefactions in the cortex and in periosteal deposits in secondary yaws appear to be more marked and frequent than in congenital or acquired secondary syphilis. The periosteal deposits and cortical rarefactions of tertiary yaws closely resemble the gummatous lesions of late congenital syphilis and tertiary acquired syphilis. The bones affected in both diseases are similar. Joint lesions appear more frequent in syphilis. The absence in yaws of osteo-chondritis so characteristic of congenital syphilis may be due to the greater age of even the youngest yaws patient (over one year) while the greater frequency of dactylitis in yaws is a quantitative rather than a qualitative difference.

None of the points differentiating yaws and syphilitic bone lesions in published papers is applicable in general to yaws. previously reported differences seem to be based on a small number of cases and were found to be non-existent over the larger number and greater variety of cases forming the basis of the present study. In short, apart from the absence of osteo-chondritis in yaws there is probably no bone lesion that occurs in one disease that may not be observed in the other. There is, however need for a thorough investigation of the bone lesions of syphilis in Africans.

BISHOP F. W. SCHRELAND L. G. & CARPENTER C. M. A Comparative Study by Electron Microscopy of the Morphology of *Mycobacterium leprae* and Cultivable Species of *Mycobacteria*. *Internat. J. Leprosy* 1948, July Sept. v 16 No 3 361-4 20 figs on 3 pl

This is an important paper illustrating varying appearances of acid fast bacilli greatly magnified under the electron microscope. The bacilli are freed

from tissue by repeated centrifuging and by taking a loopful from the top layer of the sediment, which contains most of them. Both the bacilli of human and rat leprosy were examined, together with cultivable acid-fast bacilli, e.g., *Myco tuberculosis*, *Myco smegmatis* and *Myco phlei* and the vole bacillus, and noteworthy differences between them are shown in illustrations of about 20,000 \times magnification, which should be studied by those interested. The morphological pattern of *Myco leprae* and *Myco leprae murium* is much the same, and they differ from the cultivable mycobacteria in their internal structure. Polar bodies of increased density are present in all the bacilli examined. Bodies of type A are large and opaque with no definite signs of internal arrangement, and they have been identified as nuclei of the cells, bipolar orientation is common. They were found in the bacilli of tubercle, leprosy and rat leprosy. Bodies of the B type are small and thin, generally more numerous and not so prominent as the A type. Care is necessary to exclude artefacts. Changes in morphology may be induced by exposure *in vitro* to saponified fractions of moogrol, to oleic acid, by boiling in 0.85 per cent saline and by strong bases or formaldehyde. This report is a preliminary one and further work on these lines will be awaited with interest. [Examination by the electron microscope of the acid-fast bacilli found by Moiser in cockroaches may well throw light on their real nature.]

FLOCH, H. & CAMAIN, R. Aspects histopathologiques de la lèpre en Guyane française [Histopathological Features of Leprosy in French Guiana] *Bull Acad Nat Méd* 1948, v 132, Nos 35/36, 601-5

The South American classification of leprosy of 1946 is based on histological changes, which are described in this paper as the result of 380 observations in 257 cases under treatment by the sulphones promin and diasone, in sections stained by haematin-eosin and by Ziehl's stain for bacteria. *Lepra bacilli* were found in 98 per cent of lepromatous cases, in 80 per cent of major tuberculoid, 22 per cent of minor tuberculoid and in 33 per cent of "indifferent" ones. Histological changes have confirmed in general the clinical diagnosis. Friction of cutaneous macules with caustic preparations produces infiltration with lymphocytes, histiocytes and fibrocytes and transforms anaesthetic into erythematous macules and leaves hyperpigmentation after several months. Histological examinations furnish more precise diagnostic indications than clinical ones. Moreover, histology reveals the persistence of tuberculoid changes after macules have lost their clinical tuberculoid appearance. The evolution of lesions under sulphone treatment can also be followed by means of histological examinations. The changes after treatment for a year corresponded with those described by FITZ & GEMAR [this *Bulletin*, 1946, v 43, 751]. These include a decrease in the vacuolated cells and an increase of lymphocytes and replacement of the leprosy tissues by connective tissue and decrease of the infiltration of the tissues. These modifications are most rapid and marked in recent lepromatous lesions. On the other hand, the histological appearances of tuberculoid and indolent lesions scarcely seem to be influenced by sulphone treatment. Histological examinations of sections for *lepra bacilli* are also more effective although not so quick, as in broken-up tissues, for *lepra bacilli* are found more frequently in sections if three or four specimens are examined especially in tuberculoid cases. The morphological changes in the bacilli can also be better observed in sections. Those situated near blood vessels are much more affected by sulphones in lepromatous lesions. On the other hand, the

bacilli of indifferent cases and in nerve trunks at a distance from blood vessels are little affected by sulphones. This explains the relatively slight action of sulphones in the last two types of leprosy lesions as compared with lepromatous ones.

"For the demonstration of leprosy bacilli in paraffin sections the following are recommended—(a) Fixation in Zenker's fluid (b) use of thin blocks, with minimal time in dehydrating and clearing fluids (c) staining by the oil soluble method, and (d) mounting in one of the modern synthetic mediums—clarite or permount—never in balsam.

ARNOLD H. L. Jr. The Intradermal Mecholyl Test for Anhidrosis; a Diagnostic Aid in Leprosy. *Internal J Leprosy* 1948, July-Sept., v 16 No 3 335-46 3 figs. on pl. [19 refs.]

The action of mecholyl chloride (stated to be pharmacologically virtually identical with acetylcholine) as a test for loss of sweating power in leprosy in place of pilocarpine is described in this paper. After a brief description of the physiology of sweating earlier reports on the use of mecholyl are summarized and the conclusion is arrived at that denervation of sweat glands by leprosy neuritis is the cause of anhidrosis usually affecting the most distal portions of the post-ganglionic nerve fibres. In carrying out the test equal areas of leprosy and adjoining healthy skin are painted with Minor's solution, consisting of crystalline iodine 2 grammes, castor oil 10 cc. made up to 100 cc. with absolute alcohol which dries rapidly. Then 0.05 to 0.1 cc. 1 per cent aqueous solution of mecholyl chloride injected intradermally at the border of the lesion. The whole area is quickly and lightly dusted with powdered starch from an atomizer. Within a few seconds sweat droplets appear on the functionally intact skin, which becomes black due to the iodine and starch combination. The response is negative when no sweat drops appear within the area tested. Quite exceptionally the reaction is doubtful if no more than 6 to 8 pinpoint-sized droplets can be seen on the area tested. In facial lesion it is doubtful if this test can be relied on as in the oval, hypopigmented, facial macules of *arhroma parasitica* a sweat response is liable to be absent and not one of a series of these cases has developed leprosy. Macular or tuberculous annular lesions showed the area of anhidrosis to correspond exactly with the area of innumerable and demonstrable anaesthesia and the reaction is clear cut and evident even in dark skinned patients.

VILARÓ, A. & ESTILLER, J. La radiografía de los nervios ciliares en los enfermos de lepra. [Radiography of the Ulnar Nerves in Leprosy Patients.] *Internal J Leprosy* 1948, July-Sept. 16 No 3 351-60 10 figs. on 4 pls. English summary.

The English summary of this paper states that the authors first give a brief review of the subject and then give their personal experience with this method of examination in support of the existence of the fibrous reactive leprosy of their classification. After proving the safety of their technique and the selection of thorotrast as the contrast substance they carried out experiments in the cadaver. The ulnar nerve should be exposed surgically and thorotrast injected

in an upward direction with some pressure in amounts of 1.5 to 3 cc, and they report on 8 cases of fibrous reactive leprosy and 3 of tuberculoid reactive leprosy. The X-ray pictures are difficult to interpret and they only draw final conclusions regarding the fibrous reactive cases, namely that "in classifying leprosy histologically the fibrous substratum has so dominant a role that in many of the patients there is not the slightest suspicion of a previous tuberculoid or lepromatous stage"

FLOCH, H & CAMAIN, R. Traitement de la lèpre par les sulfones (promin et diasone) en Guyane française [Treatment of Leprosy by Sulphones in French Guiana] *Bull Acad, Nat Méd* 1948, v 132, Nos 35/36, 606-10

This is a report on a trial of promin or of diasone in 52 cases for eight up to twenty months with favourable results in pre-lepromatous or lepromatous cases of a very similar nature to those already reported by others, but also dealing with indifferent and tuberculoid cases. Promin was given in daily doses gradually increased from 1 gramme to 2½ gramme and 5 gramme doses. Improvement of different degrees was observed in all, but was most marked in young subjects. Nine cases of the indifferent type were treated in young subjects, with improvement in six, no change in one and aggravation of the symptoms in two. The greatest benefit was seen in two pre-lepromatous cases. Of three tuberculoid cases in young subjects two remained stationary and one was worse. Cases which improved also showed favourable histological changes. Diasone was used in the usual doses in nine lepromatous cases with improvement in all of a similar nature to those obtained with promin. Of twelve indifferent cases in young people five improved and seven remained stationary. Of three reactionary tuberculoid cases and seven tuberculoid minor ones, nearly all in young persons, the first three lost their reactionary character, as often occurs without treatment. Of the remaining seven two were better, two unchanged and three were worse. The histological changes were similar to those after promin and reactions were not observed. Any anaemia was easily arrested by iron treatment. The lepra bacilli became granular, broke up and eventually disappeared in favourable cases and especially in the more vascular lesions. Neural cases with few bacilli were least favourably influenced by sulphone treatment.

SLOAN, N R. Effects of Sulfone Treatment on the Larynx in Leprosy. *Internat J Leprosy* 1948, July-Sept, v 16, No 3, 329-33

The author records further evidence in support of his earlier experience of the favourable effects of sulphones in leprosy laryngitis in Hawaii. During less than two years up to the middle of March, 1948, 116 patients were treated with promin, and 114 with diasone and 15 with promizole. Of 197 patients never subjected to tracheotomy, 45 lepromatous ones had the cardinal symptoms of hoarseness or dyspnoea or both, but 37 of them (82 per cent) improved apparently as the result of treatment and the remaining 8 only complained of hoarseness after short treatment. Of the improved cases at least two were saved from tracheotomy. A striking fact is that only one patient early in his treatment required this operation against 7 to 17 every year before sulphones were used. Moreover 9 patients have been able to remove their tubes, presumably as the result of sulphone treatment. Of 30 other patients, marked improvement in breathing and voice were noted in 19. Choking spells have

also been greatly relieved and chronic bronchitis due to tracheal tubes has disappeared. When a patient can inhale deeply with a finger over his tube and with little or no retraction of the suprasternal notch and the cords—if they are visible—which may not be the case—move freely the opening of the tube is covered with adhesive tape. If the patient is able to breathe naturally for some days the tube may be removed and a dressing applied under which healing may take place unless the sinus is lined with epithelium, when an operation may be necessary to close the opening. The author concludes that improvement in laryngeal lesions is perhaps the most striking result of sulphone treatment in leprosy.

FERNANDEZ J. M. M., CARBONI E. V., TOMASINO J. & GIMENEZ M. M. Hematologic Study of Leprosy Patients treated with Diamine. *Internat J Leprosy* 1948, July-Sept v 16 No 3 319-77 2 figs.

This is a careful study of the blood changes that follow the use of diamine in leprosy. Anaemia and depression were noted in 89 per cent. of cases and most marked when the daily dose exceeded one gramme. They may appear during the first few weeks of treatment and subside on withdrawal of the drug. The red cells only exceptionally decrease by more than two million and the haemoglobin to under 50 per cent. even the worst cases respond favourably to withdrawal of the drug and the use of iron, liver and vitamin B complex. Severe leucopenia was not met with and there was an increase of reticulocytes proportional to the severity of the anaemia. This indicates that the bone marrow is unharmed and the anaemia of the regenerative type. Urobilin—but not bile pigment—is found in the urine and red-cell resistance is decreased; these indicate a toxic haemolytic effect. Indirect bilirubin determination was almost always negative. The anaemia is thus benign and rarely requires interruption of the treatment especially if the daily dosage is restricted to one gramme daily.

DA SILVA J. R. Novos aspectos da terapêutica da esquistossomose mansoni. [New Aspects in the Treatment of Schistosomiasis mansoni]. Reprinted from *Boletim Medico* 1948 Dec 15 N 4 13 pp 4 refs

It is not easy to see in what respect these papers are new. The author sketches the results which various investigators of repute have reported from the use of emetine hydrochloride, tartar emetic and quinine in infections by

Sch. mansoni and enters a further plea for proof of results by examination of ova obtained by rectal biopsy—a method to be preferred to faecal examination [See this *Bulletin*, 1949, v 46, 377] H Harold Scott

KIKUTH, W & GÖNNERT, R Experimental Studies on the Therapy of Schistosomiasis *Ann Trop Med & Parasit* 1948, Dec, v 42, Nos 3/4, 256-67

Antimony compounds such as tartar emetic and foudadin and also emetine have been used in the treatment of schistosomiasis. The aim of the present therapeutic investigation was the discovery of a substance which could be given orally in the mass treatment of the infection. The researches were begun in 1932 and since *Schistosoma mansoni* develops to maturity in white mice it was employed chiefly in that host and in rhesus monkeys throughout these studies.

The vector snail was *Planorbis guadaloupensis* [*Australorbis glabratus*] and was maintained in small tanks with filtered water and sandy bottom in which various water plants were grown at a temperature of 26 to 28°C. The snails were fed on lettuce, small crustaceans, liver and earthworms. Ultra-violet irradiation at first aided cultivation of the snails but was later dispensed with. In order to infect the latter, washed eggs of *S. mansoni* from infected faeces were illuminated in water at 40°C. Miracidia soon emerged and infected snails placed in the water, one for each 30 schistosome eggs. At 26 to 28°C the development to the cercarial stage in the snails occupied 4 to 7 weeks. The cercariae generally emerged at midday under the influence of heat and light and could be counted in suspension after being killed with formalin. Instead of immersing the animal to be infected, cercariae from different snails (to ensure mixing of the sexes), were injected subcutaneously, 50 to 60 for a mouse and 200 to 300 for a monkey. Sexual maturity of the schistosomes was attained in mice in about 6 weeks, when 2 to 12 pairs were usually present. Eggs were regularly present in faeces after the 48th day and chemotherapeutic tests were then begun.

The drug was given by mouth on 6 successive days. When treatment was directed against immature worms, the drug was given on the 33rd day after infection. The excretion of eggs while the animal was alive, the presence of live worms, eggs and pigment in the liver as well as the condition of dead worms all served as criteria of the effectiveness of a drug. On testing a large number of drugs, the active xanthenes and thioxanthenes named Miracil A, B, C and D, etc., were discovered. Cure could in some cases be effected by a single dose and it should be noted that "stools do not become free from eggs until 14 days after the beginning of treatment, even when a cure has been produced". The action of miracils was more pronounced against sexually mature forms. The activity of these compounds varied in the mouse and monkey host. Because of the favourable results obtained in monkeys, Miracil D was suggested for trial in human patients, but clinical tests could not be carried out by the authors on account of the late war. Reports on the clinical use of the drug by BLAIR *et al* and WATSON *et al* have appeared [this *Bulletin*, 1948, v 45, 526, 1018]. Details of the pharmacology of Miracil D are also recorded [*ibid*, 798]. These substances cause considerable changes, especially in female worms. Intestine, gonads and yolk-cells are affected and egg-production is disturbed. Their particular action on sex-organs may explain why immature worms are less susceptible.

J D Fulton

VOGEL, H & MINNING, W The Action of Miracil in *Schistosoma japonicum* Infections in Laboratory Animals *Ann Trop Med & Parasit* 1948, Dec, v 42, Nos 3/4, 268-70

In the preceding abstract, KIKUTH & GÖNNERT report favourably on the action of certain Miracil compounds (xanthenes and thioxanthenes) against

Schistosoma mansoni infections of mice and monkeys. In the present investigation rabbit, golden hamsters and rhesus monkeys infected with *S. japonicum* by the authors' own method were used (*Acta Trop.*, 1947, 4, 1-97). When infection was established as shown by the discharge of ova, drug treatment was given by stomach tube or subcutaneously. Six different Miracid compounds including Miracid A, B, C and D were used in doses which had proved effective against *S. mansoni*. Results were judged by daily examination of faeces and later by autopsies when the worms were collected from blood vessel, chiefly mesenteric vein, and examined. Attention was also paid to the viability of ova from intestinal mucosa. After taining of the worms slight effects of the drugs were noted in sex organ, and some worms were possibly smaller than normal. They were however not destroyed nor was the discharge of ova interrupted. This finding was in contrast to the effectiveness of the same Miracid against *S. mansoni*. J. D. Fawcett

OLIVER, L. A Note on Schistosomiasis in Eastern Japan. *Amer. J. Trop. Med.* 1948, Vol. 7, No. 6, 857-75, 2 figs.

Five schistosomiasis endemic areas are known to exist in Japan. That extending along the Tone River to the north and east of Tokyo is an important rice-growing region. The presence of *Schistosoma japonicum* infestation was here first demonstrated in 1914, although it has since been found in other localities; the endemic foci have not been clearly defined. The author received information collected from available report and literature on the subject and has been able to add to this by a limited investigation of part of the Tone area. A total of 11 children, between 8 and 14 years of age, of 97 in an elementary school at Koya were shown, on the basis of a single stool examination to harbour *S. japonicum*; one of 4 children at Ono school, some 3 kilometres distant, was found infected. Cercariae of *S. japonicum* were recovered from specimens of *Oncomelania nasophora* from limited areas in the wet grassy parts of this district. The author believes the disease could be eradicated from the Koya area, as the distribution of infected snails is limited. Infected area can be avoided, and those who have to enter them to cut grass could wear protective clothing. Local instruction of the population should produce satisfactory results.

DYSCHEIDT, R. & PICK, F. Conservation de *Haemon urasoni* (Corynephium 1934) amphistome de l'homme et des primates dans des conditions extérieures à l'hôte. Preservation of *Haemon urasoni* under Artificial Conditions. *Hull. Soc. Path. Exot.* 1938, 41, Vol. 78, 490-94

Mature amphistomes (*Haemon urasoni*) were obtained from several balloons (*Pafr. sphaerus*) after autopsy and placed in various media at temperatures of 37°C, 20°C, 5°C and 0°C with the object of finding a method of keeping the worms alive outside the host. The most successful medium in which the worms remained alive for 18 days consisted of a mixture of extract of beef heart jelly and 8 per cent physiological saline at pH 7.6. The optimum temperature proved to be 37°C. The worms were also kept alive for 13 days in a simple liquid medium consisting of one part of horse serum and seven parts of Ringer solution at pH 7.6. These results are maintained to have practical value in facilitating certain biological studies and also in investigation of resistance to anthelmintics. J. J. C. Buckley

ESKOLA, O On Reticulocytosis in Anaemia Perniciosa *Diphyllobothrica* during Liver Treatment, with consideration of the various Types *Ann Med Intern Feminae* 1948, v 37, No 2, 91-115 [31 refs]

The author has studied the reticulocyte response in 19 cases of anaemia associated with *Diphyllobothrium* infection, during treatment. The worm was removed by a dose of 3.5 to 4.0 grammes of oleo-resin of aspidium (*Filix mas*) followed by Epsom salts. An injection of 5 ml (or 4 ml) of Campolon was given on three successive days and then 15 ml of liver extract daily by mouth. After an initial complete blood count and sternal puncture, differential reticulocyte counts were made daily and the sternal punctures were repeated each day up to the crisis and at the conclusion of treatment.

The author recognizes five groups of reticulocytes—(0) nucleated, (I) glomerulo form, (II) reticular, (III) imperfect reticular, (IV) maturing form with small reticular remnants only.

In six normal controls there was no change in the reticulocyte percentages during treatment. In the peripheral blood the reticulocytes ranged from 0.2 to 1.0 per cent and the ratios were groups I+II groups III+IV 1.67 to 1.115 (average 1.86), whereas in the bone marrow smears they ranged from 0.4 to 2.2 per cent with the ratios of groups I and II groups III and IV 1.11 to 1.4 (average 1.24).

In the infected cases, the reticulocyte percentage in the peripheral blood was from 0.3 to 2.8 (average 1.1), and in the bone marrow it was 1 to 4 times that in the peripheral blood. The average ratio of the reticulocyte groups I+II III+IV was 1.109 (cf normal 1.86) in the peripheral blood, and 1.36 (cf normal 1.24) in the bone marrow, that is, the maturer forms are more abundant as a result of the slow emission from the bone marrow.

During treatment the reticulocyte percentage in the peripheral blood reached its peak (reticulocyte crisis) in 3 to 8 days. In patients with less than 2.5 million red cells per cmm initially, the maximum percentage was always over 8, the highest being 22. In the bone marrow the crisis occurred on the same day or the day before.

During treatment the younger reticulocytes began to increase at a greater rate than the older ones, so that there was a shift to the left in the reticulocyte picture. This was most striking in the severe cases, in which the ratio I+II III+IV changed from 1.124 before treatment to 1.43 during treatment.

This shift reached its maximum point on the day of, or on the day before, the reticulocyte crisis. It was apparent in both the peripheral blood and the bone marrow. After removal of the worms alone, the reticulocyte crisis occurs a few days later.

L. E. Napier

ESKOLA, O Bone Marrow Picture in Early Remission of Pernicious Tape-Worm Anaemia *Ann Med Intern Feminae* 1948, v 37, No 2, 116-42 [40 refs]

A series of 6 normal controls and 19 cases of *Diphyllobothrium* anaemia were studied before and after treatment.

In the 6 normal controls, the sternal marrow counts were similar to those given by other investigators with minor but not constant variations, and no material change was observed after liver administration. The erythroblastic series were from 20 per cent to 29 per cent of the total nucleated count and of these about 70 per cent were normoblasts, most of the rest being macroblasts, there were no megaloblasts.

In 12 cases of anaemia the worms were first removed by the administration of oleo-resin of aspidium (*Filix mas*) and Epsom salts before liver extract

(Campokin 5 ml. by injection followed by 15 ml. by mouth twice daily) was given and in 7 the liver extract was given first, the worms not being removed.

In the untreated cases with severe anaemia—less than 1.5 million erythrocytes—the total erythroblast counts were from 41 per cent. to 64 per cent. of which from nil to 17 per cent. were normoblasts, 23 to 40 per cent. were proerythroblasts, and 19 to 33 per cent. megaloblasts. After liver administration the total erythroblast percentage rose further and the proerythroblasts and megaloblasts disappeared within a day or two. At the end of a week a few macroblasts only remained, over 95 per cent. of the still high total red cell series being normoblasts, and after another month 100 per cent. were normoblasts, but meanwhile the total erythroblasts had fallen to 10 to 7 per cent. of the total nucleated cell count. In the less severe cases, the changes were less pronounced but materially the same.

In the severe cases in which the worms were not removed, there was at first a reduction in proerythroblasts and megaloblasts, but later these returned to more or less their pre-treatment percentages. However there was little change in the erythroblast/leucoblast ratio and no increase in peripheral blood red cell count.

Myeloblasts were found in the bone marrow of the cases of anaemia prior to the treatment, 14.7 to 33.8 per cent., with an average of 20.5 per cent. With intensive liver treatment they disappeared on the second or the third day of treatment. In the worm-carrier cases which were given inadequate liver treatment they decreased to 0.6 to 1.7 per cent. on the third or the fourth day of treatment, after which they increased again.

The leukopoietic bone-marrow picture prior to the treatment was nearly normal, with regard to the percentages, or it showed a slight shift to the left as regards numbers, however it was increased. During intensive liver treatment, it subsided to normal level and moved slightly to the right.

Three to 7 weeks after the commencement of abundant liver treatment, a comparatively strong lymphocytosis (22 to 48 per cent. of all nucleated cells) occurred.

PEREIRA, O. Observações sobre a ação do hexylresorcinol e tetrachloretileno nas infestações pelos ancilostomídeos, *Ascaris lumbricoides*, *Trichocephalus trichiura* e sua aplicabilidade no meio rural. [On the Effects of Hexylresorcinol and Tetrachlorethylene in Ankylostomiasis, Ascariasis and Trichuriasis in Country Districts.] *Rev. Serviço Especial de Saúde Pública* Rio de Janeiro 1948, July, v 2, No 1, 47-58, 2 charts. English summary (7 lines).

Measures to combat these helminthic infestations are largely educational and sanitary engineering, but treatment of patients is a necessary adjunct. It is with the latter that the author deals here. With these drugs he treated 607 schoolchildren between the ages of 7 and 16 in various educational establishments in Vitória, Espírito Santo, and 70 in Pedra Furada, a municipality of Minas Gerais. The 677 were divided into five groups. I. Receiving one treatment with hexylresorcinol—0.4 gm. for those under 6 years [but the ages are stated to be between 7 and 16], 0.6 gm. for those between 6 and 8 years, 0.8 gm. for the 9-12-year-olds, 1.0 mg. for those 13 years or over. II. Two treatments with hexylresorcinol, with an interval of 20 days. III. One treatment by tetrachlorethylene, 2 cc. in two doses one hour apart, and a saline purge one hour after the second cc. IV. Two treatments with tetrachlorethylene with a 20 day interval. V. Treatment first by cristoids [hexylresorcinol?] and then by tetrachlorethylene after an interval of 20 days.

The results of treatment were estimated by comparing the egg-content per gramme of faeces by the Stoll-Hausheer method before and after the treatment. For a more detailed study the patients were graded according to the degree of infestation. Those with ankylostomes were put into 4 groups: (1) with less than 500 ova per gm. of faeces, (2) those with 500-2,000 per gm., (3) those with 2,000-5,000, and (4) those with more than 5,000.

For *Ascaris*: (1) Those with up to 20,000 ova per gm., (2) those with 20,000-50,000, (3) those with 50,000-80,000, and (4) those with more than 80,000.

The use of the two drugs together reduced the figures by 94 per cent. for these two helminths, 98.5 per cent. of *Ascaris*, and 93.9 of ankylostomes. A single treatment by tetrachlorethylene alone was good in mild infestations by hookworms, it was useless in a little more than 60 per cent. of patients treated. Hexylresorcinol proved excellent for *Ascaris* infestation: with one course, 10 out of 38 with more than 80,000 ova per gm. were cured, with two courses 24 out of 25.

On *Trichuris* infestations the effects were poor: whether the drugs were used singly or in sequence and in one or two courses. Only 11.7 per cent. were returned as negative.

In conclusion tetrachlorethylene has certain drawbacks to its use in rural districts: and the need for a saline purgative 3-4 or more hours after the drug is taken brings about such an outpouring of bile that the anthelmintic action is neutralized. Hexylresorcinol, however, is given once only and the patient can return to his normal activities: moreover, it is easier to take, as it is given in capsule form. The latter is therefore to be preferred for mass treatment in rural districts.

MAO C. P. Occurrence of Dog Hookworm (*Ancylostoma caninum*) in Man. *Chinese Med J* Chengtu Edition. 1945 Apr v 63A No 3 130-32, 8 figs. (10 refs.)

Report of a case stated to be the second in the literature

CATTAN R. FRUMUSAN P & COUSIN R. Syndrome de Loeffler symptomatique d'ascaridose au decours d'un infarctus pulmonaire suppure (Loeffler's Syndrome as Evidence of Ascaris Infection complicating a Septic Pulmonary Infarct.) *Bull et Mém. Soc. Méd. Hôp. de Paris* 1949 Nov 1/2, 279

A patient of 57 was undergoing treatment for an infarct of the left lung. Routine blood examination showed 7 per cent eosinophiles which increased to 31 per cent within the next month. An X-ray examination now showed a hazy infiltration of the right lung (this shadow had not been present at a previous routine X-ray examination (although evidence of the lesion in it

During this time the patient expelled the worms. Despit this and the disappearance of the X-ray signs, the eosinophilia persisted at 24 per cent accompanied by a total decrease of granulocytes (39 per cent).

The special interest of this case lies in the fact that the time from the appearance of the fleeting infiltration in the right lung to the expulsion of the worms was only 20 days. Usually in such cases one has to wait two months or more before finding ova in the stools and hence incriminating *Ascaris* as the cause of the manifestations.

CARTER, H. F. Records of Filaria Infections in Mosquitoes in Ceylon. 4 p. *Trop. Med. & Paras.* 1949 Dec v 42 Nos 3 & 4 31. 1 map & 4 figs. on pl.

These records relate to filaria infections found in mosquitoes caught under natural conditions in Ceylon and the Maldives Island. No experimental infections in laboratory-bred mosquitoes are included. The results obtained from different localities have been grouped in relation to the known endemicity of the human parasites *W. bancrofti* and *W. malayi* but it does not follow that all the infections recorded from endemic areas are necessarily of human origin; many may have been derived from domestic animals.

Three separate investigations were undertaken in the North Western Province. In the first investigation mosquitoes were collected from the villages at least once each month over a period of 3-4 days by hand-catching in the mornings and by trapping in the evenings. In the third they were collected during the night from cattle huts by pools.

In the first series, 8,500 mosquitoes were dissected. Filaria infections were found in 31 from the endemic villages and in 11 from the others. The majority were caught in cattle-baited traps. In the second series of observations, 35,000 mosquitoes were collected. Approximately 32 per cent of the total catch for both villages were obtained from houses, 10 per cent from human-baited traps, and 58 from cattle-baited traps. The predominant mosquitoes were *Anopheles subpictus*, *Culex tritaeniorhynchus*, *Aedes pallidostriatus*, *Mansonioides uniformis*, and *Aedes pipersalatus*. In cattle-baited traps the most prevalent was *C tritaeniorhynchus*. Infections with filaria larvae were found in 83 mosquitoes. 32 (in 8,325 dissected) from one village and 51 (8,932 dissected) from the other.

From May 1932 to March 1933, the village of Akaragama near Kurunegala was used as an entomological station and from observations made there is reason to believe that the great majority of filaria infections found in mosquitoes were not of human origin. Of 7,000 mosquitoes caught 24 species of culicines and 12 anophelines were represented. Approximately 2,500 mosquitoes were dissected and examined. 172 were found to harbour filarial larvae.

In the Eastern Province, Toppur, a Muslim village, is situated at the northern extremity of a large lake where *W. malayi* filariasis is severely endemic. In November 1932, of 1,944 mosquitoes collected over 70 per cent were *Mansonioides*. Filarial larvae were found in 54 mosquitoes, all but one being species of *Mansonioides*.

In the Western Province, although cases of filariasis have been reported, the data available did not suggest that it was prevalent.

In the suburban areas of Colombo, of 2,500 blood films examined 130 have shown microfilariae. All were embryos of *W. bancrofti*.

In the houses, *Culex fatigans* was the dominant mosquito. Infections with filarial larvae were found in 87, giving an infection rate of 8.8. Of three infected mosquitoes, *M. uniformis*, caught in cattle-baited traps two harboured small developing forms in the thoracic muscles, and in another (*Armigeres obthurbanus*) three mature larvae were found in the proboscis.

These investigations showed clearly that filariasis due to *W. bancrofti* is widespread throughout the suburbs of Colombo and that the essential carrier is *Culex fatigans*.

The records for the Maldives Islands relative to the most southerly of the atolls were obtained during a brief visit made in the latter part of February and early March, 1943. Although microfilariae were found sparingly in the blood of 84 residents in the daytime, no night specimens could be collected. Of 196 female mosquitoes (159 *C. fatigans*) which were examined for filarial larvae, twelve (11 *C. fatigans* and one *C. sitiens*) were infected. In *C. fatigans* collected in the village of Hittadu the infection rate was 6.6, and in the island, where elephantiasis cases are segregated, it was 8.0 per cent. *P. Manson-Bahr*

EHRLICH, W. E., SEIFTER, J., ALBURN, H. E. & BEGANY, A. J. Heparin and Heparinocytes in Elephantiasis Scroli. *Proc Soc Exper Biol & Med* 1949, Jan, v 70, No 1, 183-4, 2 figs [15 refs.]

"Microscopic examination of a human scrotum amputated because of elephantiasis showed numerous heparinocytes around lymph and blood vessels. One hundred and twenty-six mg of purified heparin per kg of wet tissue was obtained. Based on the purified material, the scrotum contained at least 16,380 I U of activity per kg of fresh tissue. These findings are further evidence that mast cells are sources of heparin. They also explain the absence of thrombosis in elephantiasis."

HERSHAW W. E., WILLIAMSON J. & BENTHAM D. S. Chemoprophylaxis of Experimental Filariasis in the Cotton-Rat. *Brit Med J* 1949 Jan 2, 130-32. [15 refs.]

The authors have shown (this *Bullet* 1949 v 46 69) that the results obtained in chemotherapeutic tests with wild cotton rats naturally infected with *L. canis* must be interpreted with caution and after due consideration of the course of infection in untreated controls. They do not consider that infections produced in rats by colonies of mites (*Liponyssus dactyl*) maintained in a rat nest and previously fed on the infected occupant are suitable for chemotherapeutic tests. In order to a void unknown factors inherent in the above method of infection they have exposed rats to controlled infection by about 20 mites per animal for approximately 24 hours as previous work had shown that they were efficient vectors. In a group of 41 rats exposed to infection in this way engorged mites were recovered from 37 of the rats and 35 of them (95 per cent) later had microfilariae in their blood. Observation has shown (this *Bullet* 1948 v 45 285) that all worms are not transmitted from the mites in their first infected blood meal. To estimate the probable number transmitted to a rat, dissections of a series of the mites was made before and of engorged mites after the transmission meal.

This method of producing controlled infection has been employed in preliminary experiments on the prophylactic action of drug. Since antrypol (Bayer 205 paramm) stilbamidine and MSb (a pentavalent antimony compound prepared by FRIEDRICH *et al* whose constitution is *p*-methylsulphonyl stibonate (see this *Bullet* 1948, 43 114) are known to be active prophylactic agents against trypanosome infection they were tested for similar properties against filarial infection in the cotton rat. Three groups of 10 rats were used and received single doses intraperitoneally of different amounts of the three drugs. They were then exposed to the bite of infected mites above, with 10 untreated controls. The infection were allowed to run their natural course and examinations were made at intervals for microfilariae and adult worms. Protection was not afforded by antrypol or stilbamidine. Rats receiving MSb were examined at intervals over a period of 4 to 9 months after exposure to infection for the presence of adult worms since no microfilariae were detected. It was found that a dose of 250 mgm. of the drug per kilo. of weight was an effective prophylactic for a period of three weeks. (See abstract below.)

YI, Chien-lung, CHAO, H, CHOW, Yen-chiao & LIU, Yun-moy **Total Serum Protein Level in Normal Adult Chinese** *Chinese Med J* 1948, Sept, v 66, No 9, 477-82 [24 refs]

"1 The total serum protein concentrations of 1,954 normal adult male and 109 normal adult female Chinese were studied

"2 It was found that the total serum protein level is within the normal range in merchants, medical personnel and most of the college students, but there was a slight hypoproteinemia in the majority of the soldiers, policemen, the servants in institutions and civil government employees

"3 The serum protein level was found to vary with the quality of the diet. A diet containing more proteins seemed to increase the total serum protein concentration."

HAEMATOLOGY

DACIE, J V & WHITE, J C Erythropoiesis with particular reference to its Study by Biopsy of Human Bone Marrow: a Review *J Clin Path* 1949, Feb v 2 No 1 1-32 58 figs (34 coloured) on 5 pls & 5 text figs [Numerous refs]

BIGGS, Rosemary & MACMILLAN, R L The Errors of some Haematological Methods as they are used in a Routine Laboratory *J Clin Path* 1948, Nov, v 1, No 5, 269-87, 14 figs [30 refs]

It has been usual for the standard of precision of a method to be based on the observations of a single expert in the particular technique, in the circumstances the error that is exhibited has often little relation to the error that might be expected from the laboratory worker of ordinary skill doing routine examinations. The authors have endeavoured to estimate the error of the method and range of "normal" readings that may be expected from a working laboratory, in carrying out the following procedures—the red cell count, the packed cell volume, the reticulocyte percentage, the haemoglobin percentage, the Price-Jones curve, the platelet count, the red cell fragility, and the whole blood coagulation time.

The results have been treated statistically and are shown in numerous tables. Some of the ranges ($\pm 2 \times$ standard deviation) are shown below—

Haemoglobin	87-107% (Haldane) 91-103% (neutral grey)
Red cell count	3.56-5.22 millions
Haematocrit	44.7-46.3 (Wintrobe)

Mean cell diameter	{ 6.58-7.50 μ (100) or 500 cell measured on one slide) 6.88-7.22 μ (500 cells on 5 slides by 3 observers)
Reticulocyte percentage	1.7-10.8 (dry) 1.0-17.4 (coverdip)
Platelets	{ 63-687 thousands (Dameshek) 134-358 (Lempert)
Coagulation time	{ 4.35-5.25 min. (Lee & White) 1.04-1.09 (Dale & Laskow)
The ranges of some of the calculated indices are —	
Colour Index	0.87-1.36 (Haldane) & 0.90-1.34 (neutral grey)
M.C.H.C	29.26-34.67 & 29.5-33.4
M.C.V	84.4-104.8 cu. μ

The authors remark in the discussion that "It may well be thought that the large errors obtained, in most cases larger than any previously recorded are proof that none but those highly skilled can carry out these investigations adequately. To some extent this is true for many of the techniques can be used with far greater precision. The Haldane method for haemoglobin estimation for example a notoriously unreliable method in routine practice can give very uniform results in the hand of one observer. And in the summary they note that "In the diagnosis of anaemia the most precise measurements found in this investigation were haemoglobin determination using oxyhaemoglobin and a neutral grey photometer the haematocrit, the mean corpuscular haemoglobin concentration and the mean cell diameter derived from the Price-Jones curve

"The red cell count has an error of 9 per cent and thus the colour index and mean corpuscular volume are too variable to record the small differences of interest to the clinician. The routine use of these indices might be restricted to the study of macrocytic anaemia in laboratories where a Price-Jones apparatus is not available

L. E. N. Japer

BIGGS, Rosemary & MACMILLAN R. L. The Error of the Red Cell Count.
J. Clin. Path. 1948, Nov. v. 1. N. 5 284-91 11 refs.

Experiment were designed to find the origin of an irreconcilable discrepancy between the opinions of two groups of workers on the degree of difference allowable between the counts made in different squares of the haemocytometer. Wintrobe and others claim that if the counts differ by more than 18 cell it is an indication that the mixing of the red cell was imperfect and they consider that such count should be discarded. Other workers have claimed that a greater difference between counts in different squares is inevitable since the red cells in a haemocytometer are subject to the Poisson distribution and that a difference up to 40 cells is possible without necessarily indicating an error of technique.

The experiment showed that there was on the part of technician a bias in favour of uniformity in replicate count. This false uniformity did not tend to increase but rather to decrease accuracy.

The authors concluded that (1) in training workers to make routine red cell counts they should not be encouraged to achieve agreement between replicate counts but to make accurate count. (2) in making red cell count a difference up to 40 cells should be allowable between the count in the 8 separate squares counted and (3) the standard error of red-cell count lies between 8 and 10 per cent.

ROBERTS, J I **Normal Haematological Standards for Nairobi, Kenya**
J Trop Med & Hyg 1948, Dec, v 51, No 12, 254-9

Total blood counts were performed on 200 healthy male European adults, drawn from military units, who had been resident in Nairobi, Kenya Colony, for at least three months. The ages of these men ranged between 20 and 30 years. Nairobi lies practically on the Equator at an altitude of about 5,500 feet. The climate is temperate, the humidity is low, the rainfall being on an average 32 inches per annum and there is a daily range of temperature as much as 30° to 40°F.

The haemoglobin was estimated with a Hellige acid-haematin haemometer (17 gm of oxyhaemoglobin in 100 cc = 100 per cent haemoglobin). The average value for these men was 20.06 gm per cent. The average red cell count was 6,039,000 per cmm, and the white cells were 7,600 (49 per cent polymorphs, 42 per cent lymphocytes). A small group of men were studied from their arrival at Mombasa, on the coast, until a month after residence in Nairobi. There was only a very slight rise in the red cell and haemoglobin values during this period. In other words, the effects of altitude are not felt for a month or longer. The well-marked absolute and relative increase in lymphocytes has been noted before at high altitudes and in the tropics generally, and is thought to be due to the greater amount of ultra-violet radiation.

The author truly states that much remains to be done in the investigation of life at high altitudes, it is still quite uncertain how far (a) altitude, and (b) the sun's rays at the Equator affect the general physiology of man, including his mental state.

PASSMORE, R. **Severe Anaemia in Indian Sepoys (Refractory Tropical Macrocytic Anaemia)** *Trans Roy Soc Trop Med & Hyg* 1949, Jan, v 42, No 4, 367-80 [12 refs]

"An account is given of 127 cases of severe anaemia with haemoglobin levels below 4.0 grammes occurring amongst Indian sepoys evacuated from the Burma campaign.

"The majority had had recent malarial infections, and just under half presented evidence of a defective nutrition. Ancylostomiasis was not frequent.

"A variety of haematological types occurred, but the majority were macrocytic anaemias.

"Many of the patients differed from cases of tropical macrocytic anaemia as usually described in that they were refractory and did not respond to either yeast or parental liver therapy. Repeated blood transfusions were found to be the most important therapeutic agent."

There were 48 deaths (38 per cent) in the series.

[The paper is mainly of value from a negative point of view, that is to say the author has shown that the anaemias encountered did not fall into any recognized groups, were of uncertain aetiology, and did not respond to recognized forms of treatment. He concludes with a suggestion that is little more than a guess and is certainly not a legitimate deduction from the data presented. It is, however, quoted below because the reviewer believes there is much truth in it.]

"Both the clinical and epidemiological evidence would suggest that we must look back into the past, before the beginning of the war, for the ultimate origin of these anaemias. It is probable that certain sepoys entered the Burma

campaign with a defence mechanism less well equipped than normal to withstand the haematological strains imposed by a period of defective rationing and a simultaneous malarial infection. In the great majority of both British and Indian men at risk the bone marrow reacted vigorously and as soon as the extra strain was removed, the blood was returned to normal. In this small minority the marrow appeared unable to react adequately and a long period ensued of impaired function often terminating in physiological failure sometimes with complete aplasia. This inadequacy of the bone marrow might be the result of repeated previous strain in childhood and youth, probably either from long standing nutritional defect or repeated malarial infections. *L. E. Napier*

SINGER K. ROBIN S. KING J. C. & JEFFERSON R. N. The Life Span of the Sickle Cell and the Pathogenesis of Sick Cell Anemia. *J. Lab. & Clin. Med.* 1948, Aug. v. 33 No. 8 873-84 3 figs. (23 refs.)

In a study of the pathogenesis of sickle-cell anaemia, the author carried out cross transfers of red cells between healthy person with the sickling trait and patients with sickle-cell anaemia. The fate of the transferred cells was followed by agglutination test. Their identity was ensured by transferring O cell to AB recipients or cells containing the A agglutinin to M or MN recipients. The survival times are shown in graphs.

The cell from healthy persons with the sickling trait when transferred into patients with sickle-cell anaemia had disappeared at the end of an average period of 120 days (the generally accepted normal life span of the red cell) graphs showing the percentage survival during the period are linear.

When cells from a patient with sickle-cell anaemia were transferred to a healthy person with the sickling trait the last surviving cell had disappeared after an average period of 74 days (actually 19, 30 & 58 days).

From this the authors conclude that the pathogenic principle operating in sickle-cell anaemia resides within the red cell themselves and that no extra corporeal mechanism can be held responsible for the haemolytic syndrome.

They also conclude that —

1. Trait cell can be used safely for therapeutic transfusion.

2. An analysis of the known facts about the sickling phenomenon shows that the sickling process which is the expression of an abnormality of the stroma does not lend itself to a satisfactory explanation of the pathogenesis of the anaemia. The hypothesis is formulated that sickle-cell anaemia develops because of an additional alteration in the cyto-skeleton which qualitatively different from the structural anomaly responsible for the sickling phenomenon.

DALAND Geneva A. & CASTLE W. B. A Simple and Rapid Method for Demonstrating Sickling of the Red Blood Cells: the Use of Reducing Agents. *J. Lab. & Clin. Med.* 1948 Sept. v. 33 No. 9 1062-8 13 refs.

The phenomenon of sickling is dependent upon the concentration of reduced haemoglobin in the blood, and appears when the tension of oxygen in the gas phase with which the blood is in equilibrium is below 40 to 45 mm. Hg. Practically all methods of demonstration, the presence of the sickling phenomenon depend on the production of reduced haemoglobin by restoring the oxygen directly by exhaustion or replacement or by excluding oxygen while the haemoglobin is reduced by metabolic processes.

The authors have devised a simple method in which the haemoglobin is reduced by a chemical agent.

"A drop of a five-fold aqueous dilution of Cevalin (approximating a 2 per cent solution of buffered ascorbic acid, also containing 0.11 per cent sodium bisulphite), or a drop of 2 per cent sodium bisulphite, $\text{Na}_2\text{S}_2\text{O}_5$, is added to a small drop of the patient's blood on a glass microscope slide. After mixing, a cover slip is dropped on the preparation and excess blood is expressed by gentle pressure in order to produce a film of blood sufficiently thin to permit inspection of individual red cells under the high-power dry objective of the microscope. With the diluted Cevalin solution, sickling of the blood usually appeared within an hour, and with the 2 per cent bisulphite solution it was often present within fifteen minutes at room temperature."

In 80 experiments, sickling was observed within 15 minutes in 9 instances, within one hour in 60, within two hours in 77, and within $3\frac{1}{2}$ hours in every instance, when the ascorbic acid solution was used.

The authors also note that formalin, but not by virtue of its reducing properties, fixes the blood in whichever stage it comes in contact with it, that is either sickled or unsickled. Zenker's fluid, however, causes a reversal to the discoid forms when it comes in contact with sickled blood. This fact is of importance when treating tissues with these fluids: the former should always be used where sickling is to be demonstrated histologically. *L. E. Napier*

VENOMS AND ANTIVENENES

GOYAL, R. K. Standardization of Dabofa and Cobra Antivenines. *Trans Roy Soc Trop Med & Hyg* 1949, Jan, v 42, No 4, 381-92

"Widely divergent amounts of test venoms are neutralized by the same amounts of their corresponding antivenines, when the mixtures are injected into different animals by different routes or in the same animal by different routes.

"There is no definite proportion between the quantity of antivenine and the amount of venom neutralized at different levels of test.

"Different batches of cobra and dabofa venoms differ appreciably in potency. It is therefore inadvisable to indicate the titre of an antivenine in terms of mg of venom neutralized. It should be stated in terms of the number of CLDs neutralized.

"A suitable method of titration of cobra and dabofa antivenines has been described."

SERGEANT, Et. De l'utilisation du DDT contre les scorpions. [DDT for dealing with Scorpions]. *Arch Inst Pasteur d'Algérie* 1948, Dec, v 26, No 4, 397-401

The author has carried out two series of experiments, one with a 20 per cent emulsion of DDT, the other with a powder containing 5 per cent DDT.

I. *Trials with Neocidol Emulsion*—A preliminary experiment [the purpose of which is not quite clear] was carried out in which 10 specimens of *Prionurus australis* (the most dangerous of the North-African scorpions) were plunged for 5 minutes in the emulsion of DDT, 10 others being submerged in tapwater for the same time. All the former died in 24 hours, all the latter survived. Next 8 were immersed for one second in the emulsion and 7 of them were dead in 3-4 days.

Trial was then made to find out whether transitory contact with the emulsion, as the passing through it to enter dwellings, would be effectual. The emulsion was sprayed on the bottom and sides of a bowl (*bocal*), and two days later

8 scorpions were placed in it—one only died and that in 3 days. Hence spraying of the ground and walls with such a suspension would afford no protection.

II *Trials with Veculol powder control*—*per cent DDT*—Two cages similar in every respect were used and each had two cartons with folded edges to offer shelter for the scorpion and the floor was sanded. Thirty scorpions were placed in each cage—those in one were sprinkled with the powder the other served as controls. The former at first appeared excited, but in half an hour settled quietly. Then toxic symptoms were observed—tremor and convulsive movements—lowering of the tail pincers open—and they died, one in 2 hours 4 more during the first day 8 on the second, and altogether 22 in the first 8 days—the other lived longer one for 41 day but by then all were dead. Of the control 3 had died in the 41 day—the average loss among scorpions kept in captivity without food.

Lastly 12 scorpion 10 adult and 2 young ones were placed in a similar cage and the powder was dusted once only at the base of the shelter and the "shelters" 13 other (10 adults 3 young) were placed in a similar but undusted cage as controls. The former showed no aversion to the DDT though their ventral surfaces came in contact with the powder. Two were dead in 2 day and 9 in 9 days—the others died on the 13th, 16th and 29th days.

The conclusion is that DDT can be used with success against *P. striatus* if a strati provided the drug is in the powder form. This scorpion is nocturnal in its movement into dwellings from without and it crawl up walls and along wooden surfaces so the powder should be spread between its haunt and bed and bedroom.

DERMATOLOGY AND FUNGUS DISEASES

BRICENO ROSA, A. L. Caratoma del Pinta. Caratoma de Pinta. *Rev. Latinoamericana Clinica y Labor.* Caracas 1948, Mar & Nov. 15 Nov. 25 26 & 27/28 255-77 291 2. [Ref. in footnote.]

The first and greater part of this contribution consists of a general description of *mal del pinto*. The paper was read at a medical congress in Mexico City in December 1947. The important part from the point of view of reader of this *Bulletin* is that which describes the differences between Venezuelan and Mexican pinta on the one hand and the Cuban form on the other. In the latter acromi is fairly frequent and palmar and plantar hyperkeratosis, and dermatitis as to how much of the Cuban pinta is really yaws or bejel, or even just syphilis and whether the Mexican (or Venezuelan) and the Cuban pintas are merely different types of the same disease. The question is left undecided.

HAUSEMAN, R. Over Mycetoma Pedis (Madura Foot). A Case of Madura Foot. *Med. Maandblad Batawa* 1949 Jan 1 v. 2, No 1 8-8 4 fig. on pl.

The English summary appended to the paper is as follows:—

"Description of a case of mycetoma pedis (Madura foot) from the island of Lombok."

SALVI, S. R. & HORTER, C. A. Factors Influencing Haptoglobin Formation. *J. Biol. Chem.* 1949 Nov. 56 N. 3 541-6 1 fig. 11 ref.

By means of a complement fixation test (which preliminary studies showed to be more satisfactory than the usual skin test) the conditions influencing haptoglobin formation by *H. stylus* & *H. salinus* were investigated.

In a medium consisting of *L*-asparagine, 14 gm, glucose, 10 gm, glycerol, 25 gm, magnesium sulphate ($MgSO_4 \cdot 7H_2O$), 1.5 gm, dipotassium phosphate (K_2HPO_4), 1.31 gm, sodium citrate, 0.9 gm, ferric citrate, 0.3 gm, water to 1 litre, the maximum yield of histoplasmin was obtained after 8-10 weeks at room temperature. Replacement of the glucose by 10 gm of cellobiose, dextrin, starch, or glycogen increased the production of histoplasmin from four to eight times. An initial pH of 7.0-8.0, a surface to volume ratio of near unity, and a temperature of 25°C were found to be optimal for histoplasmin production while light, submerged or surface growth, and strain of the fungus were not critical factors.

G C Ainsworth

EMMONS, C W & ASHBURN, L L. Histoplasmosis in Wild Rats. Occurrence and Histopathology. *Pub Health Rep* Wash 1948, Oct 29 v 63, No 44, 1416-22, 2 figs

In a previous paper, EMMONS, BELL and OLSON [see this *Bulletin*, 1948, v 45, 207] described the discovery of histoplasmosis in 10 wild rats and one mouse. The present report deals with the same group of animals, to which 6 more rats have been added. These 16 rats were among 565 trapped in Loudoun County, Virginia, in an area in which human and canine cases of histoplasmosis had occurred. In all cases the diagnosis of the infection in the rats was based on the isolation of *Histoplasma capsulatum* from the spleen and liver and less frequently from the lungs. Macroscopic lesions were seen in only four of the animals, but all of these were not attributable to histoplasmosis. Microscopically, the characteristic lesion of histoplasmosis was an "epithelioid" cell granuloma with a few macrophages and fibroblasts and rarely a giant cell. These granulomata, which occurred chiefly in the spleen, liver, lung and adrenal, were sharply defined and measured from 30 to 200 μ in diameter. *H. capsulatum* was seen in sections from the lesions of nine of the animals.

SMITH, C E, BRARD, R R & SAITO, Margaret T. Pathogenesis of Coccidioidomycosis with special reference to Pulmonary Cavitation. *Ann Intern Med* 1948, Oct, v 29, No 4, 623-55, 5 figs [44 refs]

This is an important paper which should be read in the original.

In reviewing the pathological features of coccidioidomycosis, the authors state, in relation to the grave but relatively uncommon disseminated granulomatous form of the disease, that "Army experience also has indicated that dissemination usually occurs soon after the infection is acquired, frequently within a matter of weeks and infrequently after months". This is in marked disagreement with the view expressed by FORBUS and BASTEBREURTJE (*Military Surgeon* 1946 v 99 653), that disseminated coccidioidal granuloma is a reinfection phenomenon which may develop at any time up to about ten years after the original infection.

Pulmonary cavitation was found in from 2 per cent to 8 per cent of different series of cases of clinical coccidioidomycosis in the U.S. Army and about 90 per cent of the cavities were single. Cavitation may develop in pneumonic patches within the first few weeks of the illness or up to some months after infection, and in more than half the cases it gave rise to no observed symptoms but was only discovered in the course of routine radiography. The cavities tend to close spontaneously and in the early stages, complete rest until the general symptoms have subsided hastens the healing processes, but a cavity may sometimes persist and if it causes symptoms may require treatment by phrenic crush or even a more drastic surgical procedure. Cavitation is not caused by a progressive local coccidioidal lesion, in fact, it is usually associated

with a demonstrable degree of acquired immunity and it may be accepted as a good prognostic sign for the authors. We have never seen dissemination occur in a patient with coccidioidal cavitation.

J. T. Duran

RECTOR L. E. & RECTOR Eleanor J. Coccidioidomycosis in the Salivary Gland of the Townsend Mole. *Am. J. Trop. Med.* 1943 Sept., v. 23 No. 5 707-9 2 figs.

Two Townsend moles (*Scapanus townsendi*) were caught and killed in the Gamblers District of Seattle Washington State in 1934. The salivary glands were removed, fixed in 95 per cent. alcohol and examined for intranuclear or cytoplasmic inclusions. No inclusion bodies were found but aggregations of fungal cells were seen in the parenchyma of the gland. These fungal cells were spherical and measured on an average 15.3 to 17.1 μ in diameter the limit being 12.3 and 20.5 μ . Budding forms were not seen and there is no reference to endospores. Two competent pathologists appear to have identified the fungus as *Coccidioides immitis* but this diagnosis is difficult to reconcile with the authors' description of the parasite and the photomicrographs of the gland section. It seems significant also that although 15 years have elapsed since this apparent discovery, no further record of coccidioidal infection in the north western United States has appeared. Another fungal parasite of desert rodents *Haplosporangium parvum* which might be mistaken for *C. immitis* has a much wider geographical distribution and has been found as far north as Alberta Canada.

MUENDE I. Treatment of Fungus Diseases of the Skin. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1943 Nov. v. 4, No. 3 216-22.

This paper should be read in the original by all who are interested in the control of ringworm infection.

Despite the great amount of research on the chemotherapy of the dermatophytoses and the very numerous fungicides available it must be admitted that the drug treatment of some forms of tinea capitis and tinea pedis is frequently unsatisfactory. In the main treatment tends to be based more on physical than on chemical methods, the epilation of the nail and the use of keratolytic agents play a major part in therapy. Dr. Muende gives timely warning against the use in certain forms of athlete's foot, of irritant or excessively stimulating fungicides even those of recent introduction, because of the danger of causing sensitization or bacterial dermatitis. However stimulating drugs such as chrysarobin and the much advertised phenyl mercury compounds are valuable in the treatment of chronic and resistant infections. The propionate and undecylenates from which much good was expected in cases requiring prolonged treatment have proved rather disappointing.

On the important question of the need for X-ray epilation in the treatment of tinea capitis Dr. Muende points to the good results obtained by topical application of mild chrysarobin ointment followed by mechanical epilation of the loosened hairs when the infecting species is *Microsporum* and he refers to the recent success claimed by Braun and others in the treatment of *Microsporum audouinii* infection of the scalp by the application of phenyl mercuric nitrate in a carbonyl base.

For established onychomycosis a solution of the nail plate combined with the application of fungicides to the nail bed will be the treatment of choice. The temporary avulsion however frequently followed by recurrence of the disease in the new nail and permanent avulsion of the finger nail is aesthetically

objectionable. Further research should be made on the use of fungicidal natural antibiotics, and another line of research recommended is on the use of fluorescent dyes which, when fixed by the fungus, render it highly susceptible to the action of ultraviolet rays, but dyes which fluoresce to the more penetrating rays of the red end of the spectrum may be even more valuable.

For the prevention of tinea capitis, diagnosed cases should be isolated and treated and all contacts should be kept under observation, with repeated examinations, for 2 or 3 weeks to detect carriers and new infections. The control of the more widespread tinea pedis is impracticable except in the case of more or less closed communities.

HEAT STROKE AND ALLIED CONDITIONS

GALVÃO, P E Human Heat Production in relation to Body Weight and Body Surface I Inapplicability of the Surface Law on Lean Men of the Tropical Zone *J Applied Physiol* 1948 Nov v 1, No 5, 385-94, 2 figs [11 refs]

GALVÃO, P E Human Heat Production in relation to Body Weight and Body Surface II Inapplicability of the Surface Law on Well Proportioned Men of the Tropical Zone *J Applied Physiol* 1948 Nov v 1 No 5, 395-401, 2 figs

CROWDEN, G P A Survey of Physiological Studies of Mental and Physical Work in Hot and Humid Environments *Trans Roy Soc Trop Med & Hyg* 1949, Jan, v 42, No 4, 325-35, 2 figs [20 refs] Discussion 336-40 [WEINER, J S, McROBERT, G, ALAKIJA, O B, TIDY, H, WATTS, J C]

In this very interesting paper the author gives a review of physiological and psychological studies of the effects of work in hot places. Starting with the early observations of BLAGDEN and FORDYCE (1774) he attempts an appreciation of the work of various researchers. Much work on reactions to heat and humidity has been carried out with the purpose of helping men to face difficult climatic conditions in times of war, and the primary object of this paper is to interpret the knowledge so gained so that its use may contribute to human welfare in times of peace.

Much of the more recent work deals with the physiological or mental efficiency of carefully selected subjects, physically fit and young. Crowden very pertinently points out that these subjects were in an optimum condition of health, and had a maximum capacity to withstand fatigue, and that in attempting to apply the experimental result to the general population this very important fact must be borne in mind. He feels that the observations should be carried further to ascertain the reactions of a representative selection of a normal population.

After the presentation of the paper there was an interesting discussion. Sir George McROBERT made biting comment on the way in which English officials in the tropics bedeck themselves with the habiliments of England and, worse, their attempts to induce indigenous inhabitants to follow suit. Dr J S WEINER discussed the effects of air movement and radiant heat, the effects of acclimatization, and tropical anhidrosis.

Replying to the discussion, the author referred to the reduction in air movement within a mosquito net, and the consequent increase in effective temperature, and to the need for further studies of tropical clothing. Thomas Bedford

MISCELLANEOUS DISEASES

MACKAY D. *Cancerum Oris among African Natives. Memoranda. Brit Med J* 1919 Feb 5 223.

The prognosis of this condition has been regarded as almost hopeless. An infection with spirochaetes and fusiform bacilli is considered to be the probable cause.

The author did not see a single case while working in Great Britain in a highly industrialized area, but in the Serengeti district of Northern Rhodesia he met with six cases in three years three of these being fatal. Of the two patients who recovered one was treated by extensive resection of the gangrenous area followed by plastic repair the other with penicillin and this case is reported in detail.

A girl aged about two years was admitted to hospital on Oct 3 1917 clinical examination showing a typical early case of cancerum oris. The next day the brother (the also aged four was admitted monitored with the same disease and died within 24 hours.

The girl was treated at first by swabbing with a strong solution of potassium permanganate but the ulceration progressed. On Oct 10 treatment with penicillin was begun, 10,000 units in aqueous solution being given intramuscularly every three hours. After the third injection, treatment was stopped for twelve hours owing to superstitious objections by the parents. Injections were then resumed and continued until 500,000 unit had been given. Improvement was shown after 24 hours and after three days all signs of infiltration of the surrounding tissues had disappeared and the ulcer showed a clean and healing surface. Recovery was uninterrupted and the patient was discharged on Oct 27. It seems probable that the male child infected the female.

In none of the cases was there a previous history of specific illness and the author thinks that the chief cause is the poor diet and unhygienic life of the African. It may be noted that the probable causal organisms of cancerum oris are similar to those found in tropical ulcer which is very common in the district. C. F. Skellern

HAN T N. Recidiverende zweer aan vulva en vagina gepaard met stomatitis aphthosa en conjunctivitis catarrhalis (syndroom van Behcet) bij een Chinese vrouw. Behcet's Syndrome in a Chinese Woman. *Med Maandblad Batafa* 1949 Jan. I v. 7 No. 1 13 17 "7 refs.]

The English summary appended to the paper is as follows —

"A 44 years old Chinese woman suffered within a year of 10 attacks of aphthous ulcerations situated on the oral mucosa and associated with multiple sharp-edged ulcers of vulva and vagina, and a slight form of conjunctivitis catarrhalis with photophobia. The lesions appeared simultaneously or alternately at intervals of 4 to 6 weeks.

Differential diagnosis between ulcus molle REITER's triple syndrome amoebiasis STEVEN'S-JOHNSON'S syndrome and BIRKET'S syndrome is discussed. According to the author his case is identical with BIRKET. Owing to the fact that the pathogenesis still remains obscure it is interesting not that patient husband is suffering from lung tuberculosis, that her blood globulin rate is too low (0.9%) and that she shows gastro-intestinal disturbances (horlogrignu and roctus) and anaemia.

GREEN R. & MANJESKAR D S. Abscess Cases of Meliodosis. *Brit Med J* 1949 Feb. 19 388-11 2 refs.

The authors describe a case of meliodosis in an Indian artisan in which the only manifestation was a suppurating cervical gland. Complicated resolution

followed treatment by aspiration of the pus and a course of sulphapyridine by the mouth. Other workers have described similar cases in which there was no fever or other constitutional sign, the infection being confined to a solitary abscess or to superficial skin lesions.

The present authors studied the sensitivity of a strain of *Pf whitmori* to various sulphonamides *in vitro* with results in favour of sulphathiazole and sulphadiazine. The organism is not sensitive to penicillin in concentrations attainable in the blood, this antibiotic has been advised for local treatment. With the use of the ring-cup technique, streptomycin and polymyxin in concentrations up to 1,400 μ gm per ml failed to inhibit the growth of *Pf whitmori*. Chloromycetin, however, in concentrations attainable in the blood (60 μ gm per ml) gave a high degree of inhibition.

The conclusion is that chloromycetin, alone or in combination with sulphonamides, is worthy of clinical trial in melioidosis. J C Cruickshank

MINISTRY OF HEALTH. Memorandum on Measures for the Control of Mosquito Nuisances in Great Britain. Memo. 238/Med. Revised Nov 1948. 35 pp. 2 maps & 2 pls. 1949 London H.M. Stationery Office [U]

This memorandum was first published in 1940 and revised and reprinted in 1942 [this *Bull* n 1943 v 40 413]. The present revision retains practically all the subject matter of the earlier editions. A few deletions have been made in the section on Control: this has been modified and brought up to date by the inclusion of information on the use of DDT and BHC ("Gammaxene") against mosquito adults and larvae and on the use of dimethyl phthalate as a repellent.

The memorandum mentions that only a few cases (number not stated) of indigenous malaria occurred in the British Isles immediately after the second world war [but see this *Bull* n 1948 v 45 21]. D S Hertram

DAHL, A. H. New Plans for Vector Control in California. *J. National Malaria Soc.* 1948 Sept v 7 No. 3 231-5.

The diseases carried by arthropods which occur in California are encephalitis, fly-borne diseases, malaria, plague, Q fever, relapsing fever, Rocky Mountain spotted fever, tularemia, and typhus fever. A new department known as the Bureau of Vector Control has been established to organize the prevention of these diseases. Its first action was to review the importance of each, the state of fundamental knowledge of the vector and the reservoir and the sufficiency of past surveys, control programmes and control demonstrations. The result of this review is set out in a table from which it is clear that work could be better balanced, and proposals are made for the increase of some items of work such as survey of encephalitis, fly-borne diseases, Q fever, relapsing fever, Rocky Mountain spotted fever and typhus and for the decrease of others such as survey of plague and tularemia.

The future policy of the Bureau will be guided in this analysis of the problem, and by an advisory committee. It will have a staff of 40 persons including sanitary engineers, entomologists, sanitarians, and rodent control staff in addition to the entomologists from the Federal agency already in the State. G. Macdonald

ANDREWS, J. M. Control of Diseases propagated by Arthropod Vectors. *Bol. Oficina Sanitaria Panamericana.* 1948 Nov v 77 No 11 948-1007 [10 refs.]

In an opening address to the Pan American Sanitary Conference of 1949 the author briefly reviews the prospects of securing efficient control of 141 forty diseases carried by arthropods. He concludes that battling world conflicts especially those in which the end would seem to justify such ruthless means as a biological war is never reason to believe that the present trend of arthropod-borne diseases should continue downwards. Some of these diseases seem to be susceptible to eradication technology certainly within the more advanced countries of the world. G. Macdonald

The authors describe tests comparing the effectiveness of DDT, benzene hexachloride, chlordane and chlorinated camphene both in space sprays (1

LABORATORY PROCEDURES

SUTER R. Action des produits mouillants sur la coloration des parasites sanguicoles. (Note préliminaire) [The Use of Wetting Agents in the Staining of Blood Parasites.] *Ann Parasit Humaine et Comp* 1948, v 23 Nos 3/4 220-21

Swiss work had previously shown that thiodan blue was an ideal and rapid stain for certain blood parasites (trypanosomes, spirochaetes and leptospires) (see SUTER in this Bulletin 1947 v 44 628). The stain is composed of methylene blue and saponin which form a stable combination. The saponin haemolyzes the red cells and thus makes it easy to detect the organisms even when very few are present. Under ordinary illumination the parasites stain blue but under the dark ground, the curious Berek effect is produced and the organisms exhibit an intense and brilliant red colour.

The author discovered that saponin could be replaced by many other wetting agents as long as they possessed a haemolytic action. Two were found which acted nearly as well as saponin—Desogene (a quaternary ammonium compound) and Eriopon (an amide prepared by Geigy). P C C Graham

GOLDMAN M. A Single Solution Iro-Heamaterylin Stain for Intestinal Protozoa. *Stn Technology* 1949 Jan., v 24 No 1 57-57

Two solutions are prepared —

Solution A—A 1 per cent. solution of hematerylin in 95 per cent alcohol prepared by diluting a 10 per cent. stock solution of the dye in 95 per cent alcohol. Ripening is unnecessary.

Solution B—Ferric ammonium sulphate 4 gm. glacial acetic acid 1 cc., concentrated sulphuric acid (sp gr 1.8) 0.12 cc. in 100 cc. of distilled water.

Equal part of freshly prepared solutions of A and B are mixed and kept for a few hours and filtered before use. The mixture should be discarded if it becomes greenish black in colour instead of dark brown.

Faecal films are fixed in Schaudinn's solution plus 5 per cent acetic acid, for 1 hour, washed in 70 per cent. spirit plus iodine for 5 minutes and then in 2 changes of 50 per cent. spirit for 3 minutes each. The stain is applied for 3 minutes and washed off in tap water for 5-30 minutes. The film is finally dehydrated, cleared and mounted.

Intestinal protozoa are stained blue or grey and show the usual features brought out by the Heidenhain technique though with less precision. The method is recommended for routine diagnostic purposes. P C C Graham

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

COLONIAL OFFICE. Report of the British Guiana and British Honduras Settlement Commission. Cmd 7333. (Eva S. Geoffrey (Chairman).) pp. viii+359 10 maps (9 in pocket and 1 in text) & 31 at figs 1948 London H M Stationery Office 7 6d

The public health as well as the social and economic structure of the West Indian island, reflect the difficulties caused by excess of population, the density of which varies from 1,200 to the square mile in Barbados to little below 300 in Jamaica and Trinidad. In contrast the enormous territories of British Guiana and British Honduras are virtually unpopulated, with densities 1.4 and 7 per square mile respectively. In each of these last two there is a small, densely populated area with a vacant hinterland isolated by natural barriers of difficult country which has prevented free access.

There have been many suggestions for the use of these vacant lands, and this Commission was instructed to report on the possibilities of settlement in them "having regard to the recommendations made by the West Indian Conference in 1944 and 1946 regarding the need for study of the Guianas and British Honduras as an aid to the solution of the problem of over-population in the West Indian island territories." The report makes it clear that there is no insuperable barrier to settlement. Medical problems are examined in detail. An analysis of the history of British Guiana shows that until recently the death rate exceeded the birth rate and the population was only maintained by regular immigration, though some doubt is thrown on the normally-accepted estimate of the extent of the natural decrease. In recent years a natural increase has replaced the decrease and it is reliably estimated that the population will increase by 40 per cent in the next 15 years. Malaria, once the greatest cause of mortality, is no longer so, and there is no other serious endemic disease which cannot be brought under reasonable control either in the coastal lands or in the interior. An able analysis of the effect of the climate on Europeans shows that there is no reason why they should not live and work there in what is called sporadic or dependent settlement, as technical advisers and administrators but close or independent settlement by them is not advisable.

The Commission considered the two alternatives of encouraging the independent settlement of smallholders and of large-scale commercial plantations without considering any intermediate type such as co-operative farming on an economic scale. The decision is in favour of encouraging agrarian settlement for the production of export crops on a plantation, not a smallholding, basis, immigration being timed to meet the needs of the various projects. Most immigrants would arrive as contract employees of individual concerns, the large employer so far as possible providing housing and social services, though Government would care for smallholders in this way.

The many difficulties are reviewed and it is concluded that it should be possible over a period of some ten years for the two Colonies to absorb about 100,000 men, women and children, including about 25,000 adult workers. Such migration would have to begin slowly and extend over many years and would lead, it is hoped, to a "chain reaction" of economic progress in the economy of the two Colonies which would continue to absorb immigrants.

[The reviewer cannot avoid the feeling that the Commission has overlooked the instruction to consider the matter as an aid to the solution of the island population problem. Though the health, economics and population of these two Colonies are closely studied there is no factual matter besides a brief introductory note on the relation between the rate of increase in the population in the islands and the absorptive capacity of the new countries. Details are given of the proposed Development Corporations and of the intentions for agricultural development, but the estimate of the number who could be absorbed is baldly stated in the introduction without any supporting data in the text on the rate of migration or the manner in which the total has been estimated. It may be that the Commission considers that immigration would only start on any material scale in the last couple of years of the decennium, and a rapid increase might be expected thereafter. Perhaps the figures given refer to direct employees and their dependents only and the total would be swollen by an equal number engaged in trade, transport, ancillary services and the professions. Perhaps a plantation area is considered only as a nucleus for the growth of those services needed by a farming community which would appear around them. But on these points and similar relevant ones the Commission throws no light. The question whether settlement in the interior is possible is adequately answered in the affirmative. The question whether such settlement could have any material effect on the population problems of the islands is left unanswered.]

FORD J & HALL R. de Z. The History of Karagwe (Bakoba District)
Tanganyika Notes & Record 1947 Dec. No. 71 77 pp 1 map
 [29 refs.]

The authors are interested in the history and especially in the early epidemics of a part of Bukoba a district in Tanganyika lying along the south-west corner of Lake Victoria.

Bukoba is inhabited by two very different tribes. The Bahima who are aristocratic pastoral people Nilotic in origin and the Banyambo who are agricultural people and Bantu. In the latter part of last century there was a long period of serious raking wars and disturbances, aggravated by European penetration though the authors state that German occupation was not seriously harmful to the social organization of the country. At the same time there was a serious uncontrolled epidemic of smallpox which was apparently a disease new to the country and chiggers (*Trombidium*) arrived from West Africa. The people did not understand how to deal with the chigger many men were crippled and in some places harvest were lost because the people were suffering from chigger ulcers and could not get the crops in.

The country had been prosperous for grass was good and there were plenty of good cattle. In 1890 or 1891 there was an immense epidemic of rinderpest with terrible destruction of the cattle. The Bahima were compelled to fall back on the crops produced by their agricultural neighbours and dependents. They lost their social position by doing so but were saved from death by starvation. It seems that until the end of last century tsetse flies were absent then *C. morsitans* entered the country apparently from the south and by 1901 had advanced at least seventy miles crossing the border into Ankole where cattle died and trypanosomes were found.

The result of all these disasters was serious loss of population and the people who remained were socially disorganized. As the cattle died the grass country went back to bush and became occupied by tsetse. At present the reduced population is concentrated and the people are somewhat crowded together a menace again to the risk of sleeping sickness. The authors point out that there have been many causes operating to ruin this good land. Among them is the fact that the indigenous society was not well adjusted to meeting its own (a somewhat indefinite diagnosis).

The authors have assembled a large amount of information which is of necessity fragmentary. They seem to have interpreted it in a reasonable way. The result is a refreshing and interesting paper. P. I. B. van

MINISTRY OF SUPPLY & DEPT. SCIENT. & INDUST. RES. Tropical Proofing
 Protection against Deterioration due to Tropical Climates. Compiled by
 the Directorat of Chemical Research and Development pp. 37
 1949 London H.M. Stationery Office 2s.

The work was originated by the Ministry of Supply in the war period. Studies were made on the destruction of military equipment. It mainly refers to insect and fungi and tropical climates. It is on method of protecting equipment or designing it in such a way as to reduce damage. Work on these subjects is still in progress in Nigeria.

The present pamphlet is brief and rather general. It deals with attack by fungi and insects and discusses the particular problems of great variety of materials among them paints, leather, wood, textiles, paper and paint. The special problems produced by optical and electrical instruments are also considered. Damage done to building, ships or other large structures or food stuffs is not included.

The account of fungi covers four pages. The main biological characteristics of the moulds are introduced and attention is directed to conditions of temperature and humidity which are generally most favourable to them. It is pointed out that some moulds may interfere with the performance of optical instruments owing to the presence of their hyphae on the surfaces of lenses or mirrors; others may grow through the insulation of electrical devices or bridge gaps in circuits. Other moulds grow, as is doubtless well known, on organic materials of many types, and some of the species are particularly associated with certain substrates. The section on fungi is concluded by brief and rather general recommendations about the reduction of damage.

It is considered that damage by insects is a relatively minor matter and the whole subject is dealt with in about a page and a half. This seems inadequate for instance it is not possible to deal with the biology of termites and the damage they cause in one paragraph. One observes also that in describing the destruction of woollen materials by beetles there is no reference to the organic insecticides.

A number of other criticisms might perhaps be made. One would expect some reference to the possible toxic action of certain of the fungicides to the men who apply them. We feel also some doubt about a list of timbers which are said to be resistant both to fungi and to termites—it would surely be preferable to distinguish two groups of timbers and if possible to identify them by their scientific names. In the present list each timber is given only a single African or Asiatic name. Parts of the pamphlet appear to have been drafted by someone who experienced great difficulty in expressing his meaning in English, though the sympathetic reader will generally divine what is intended, as in the following example—

“ stores containing rubber parts should, therefore, be given a fair chance and should not be exposed unnecessarily to heat, brilliant sunlight or to other adverse conditions. An interesting, and unexpected, example of this is the formation of high concentrations of sulphuric acid in imperfectly drained hose, due apparently to certain strains of thiophilic bacteria.”

The subject of the pamphlet is without doubt very important. A greatly extended edition of it with a fuller list of references might well be a very valuable work.

P. A. BURTON

IRIARTE, D. R. *Estudios entomologicos y parasitologicos* [Entomological and Parasitological Studies] 253 pp., numerous figs. & 3 coloured folding pls. 1948. Caracas. Tipografia Americana.

This is a collection of articles, most, if not all, of which have been published before and all but two have already received notice in this *Bulletin*. The longest is the first, on the Simuliidae of Venezuela. In this the author reviews the history of the Family and gives an account of their bionomics; one section is given up to the question of their classification and contains a description of the 11 species already found by the author in Venezuela and a useful key for their identification. Six other species have not been found by the author himself, of these he therefore, gives the original descriptions. Line maps indicate the distribution of these species. Finally, there is a fairly comprehensive bibliography on the subject. Other papers, dealing with cutaneous leishmaniasis, Chagas's disease, carate and paracoccidiosis have already been abstracted in this *Bulletin* [1940, v. 37, 105, 1945, v. 42, 655, 1946 v. 43, 1128, *et al*] and need not be again referred to.

H. HAROLD SCOTT

BOOK REVIEWS

SIRRY, George (M.B. B.S. (Srd.) Acting Senior Pathologist, Colonial Medical Service? *Nutritional Macrocytic Anaemia*. 78 pp. 13 pls. (3 coloured & 2 maps) & 16 charts 1947. London: Crown Agent for the Colonies 4 Millbank, S.W. 1. [£1 1s. 0d. Rs. 14.]

This volume bears the date 1947 and was received for review in December 1948 but it is only fair to the prospective reader and to the author to say that it contains intrinsic evidence of having been a very long time in the press—for example there is only one reference dated 1943 and none with a later date and the words "follic acid" were not encountered.

With the limitations naturally associated with the above facts, the book constitutes a useful but of course far from complete summary on nutritional macrocytic anaemia and gives some indication of the type of case that is encountered in Mauritius. However if this information had been condensed into a paper of 3 000 to 5 000 words and published in a medical journal at the end of 1943 or early in 1944 it would have constituted an up-to-date and far more useful contribution to the literature on this subject.

The condition is common in Mauritius and most common in the highly malarious coastal belt but no general survey has been done. The author found macrocytes in 20.3 per cent of 300 blood slides taken from children.

The staple diet of members of the labouring classes (from among whom all the cases came) is parboiled rice 485 grammes daily with pulses (40 grammes) bread (67 grammes) and fruit and vegetables when they are in season and cheap. They consume about 16 grammes of fat mostly vegetable in origin. Meat is eaten rarely less than once a week, and fish "occasionally" but milk is drunk regularly. It is stated that this is usually diluted but there is no indication of the average amount taken. The common vitamin deficiencies are A and B groups.

Splenomegaly was found in 75.9 per cent of the cases and the usual cause was malaria. The van den Bergh reaction was 1.0 norm or over in 22.9 per cent and 0.5 norm in 51.1 per cent of cases of the former group 90 per cent of patients had enlarged spleens.

Malaria appears to exert its destructive influence partly by direct parasitization of the red cells partly by a toxic effect on the bone marrow but mainly by hypertrophy of the reticulo-endothelial system, which then attack the abnormal erythrocytes. This statement is not based on his reported experience.

While the disease in its severe form does appear to be definitely more common in females particularly during pregnancy there is no evidence that there is any particular age or sex distribution of mild or moderately severe nutritional macrocytic anaemia. Thus, in Mauritius macrocytosis and mild clinical anaemia was found commonly in children under 10 years and the male:female ratio was approximately 1:1.

"Eighty per cent of the local cases were Hindus but the percentage of Hindus in the population group is not here stated elsewhere it is noted that "the labourers" are mostly Hindus.

The months of highest incidence of severe anaemia are June, July and August whereas the malaria season (from February to May). The author thinks that the former disease is dependent on the latter.

The pathology of the disease is discussed from the literature or new data are supplied.

The clinical picture is described. It is not always clear whether the author is giving his own experience or quoting from the literature. In his cases

abdominal pain is common (50 per cent) and vomiting less frequent (25 per cent) Wasting is unusual Tachycardia is usual but not hypotension Nervous symptoms are few and there was never any cord involvement

Some mean blood findings in the cases were as follows —

Haemoglobin, grammes per cent — 4.08 (1.41 to 12.85)
 Red cells, per cmm — 1,129,000 (lowest 375,000)
 Mean corpuscular haemoglobin — 37.35
 Mean corpuscular—haemoglobin concentration—28.8 per cent
 Mean corpuscular volume 134.7 cu μ
 Mean corpuscular thickness—4 of 10 above 2.5 μ
 Mean corpuscular fragility (non-pregnant cases)—0.349 NaCl
 Leucocytes per cmm — 4,530
 Platelets per cmm — 77,038 (17,850–154,840)

In the sternal puncture smear the author found normoblasts and megaloblasts the latter were of about the same average size as those found in pernicious anaemia [and larger than other workers have reported in nutritional macrocytic anaemia] The ratio of red/white precursors was about 1/1

The Price-Jones curve shows a shift to the right in most cases

The three curves illustrated show a higher peak and narrower base than is typical of pernicious anaemia

The mortality rate was approximately 18 per cent, late application for treatment was the main cause of this high mortality The author devotes a chapter (or rather a part) to treatment, but again it is difficult to follow what he himself actually used in his cases, except that in six (4 males and 2 non-pregnant females) he used a locally prepared yeast mixture, a by-product of a local sugar factory These six cases are reported in detail and, in 4, graphs of the blood counts are given all showed rapid and satisfactory improvement [However, the treatment of pregnant women constitutes a much more difficult problem] The author refers to whole liver, liver extracts, and Marmite, but not to proteolysed liver or folic acid He also mentions blood transfusion, but not apparently from personal experience in this disease

There are three short appendices on Mauritius, with a map, on technique, in which he notes the methods he used and a table of the blood findings in his fifty cases

The book is generally speaking well produced and contains a number of illustrations, including two good coloured plates of megaloblasts, but it is not entirely free from printing (or clerical) errors e.g., there is a reference to WILLS and MAWSON which should obviously be MILLS and MAWSON, and Machanda, Manchanda, and Manchunda, are variants used to indicate one worker

MATHIS, C [Membre correspondant de l'Académie de Médecine, etc] & PONS, R [Ancien Chef de Laboratoire à l'Institut Pasteur de Saïgon, etc]
 Manuel de Pathologie Exotique [Manual of Tropical Diseases] pp viii+642, 10 figs & 1 coloured pl 1948 Paris Presses Universitaires de France, 108 Boulevard Saint-Germain [35s 6d]

This book is intended primarily for the use and guidance of medical practitioners in the Tropics It covers the whole range of diseases commonly dealt with in text-books of tropical medicine In every chapter attention is mainly concentrated on clinical signs and symptoms, diagnosis and treatment Descriptions of laboratory techniques essential to the diagnosis of so many tropical diseases are confined to those which the average practitioner should be capable of carrying out himself Preventive measures receive but scant attention Notes concerning the geographic distribution of diseases relate almost entirely to French overseas possessions

The book is clearly and concisely written and very well produced. It is evidently based on wide personal experience but the authors claim that their manual takes account of recent advances in knowledge of the aetiology and treatment of tropical diseases can hardly be substantiated. Omissions are very numerous—for example new methods of malaria therapy receive bare mention and the yellow fever chapter is very inadequate.

Rapidity of progress in the domain of tropical medicine has been so great during the last ten years that the difficulties attendant upon the production of an up-to-date manual are almost insurmountable. The major part of this volume would appear to have been written several years ago. Very considerable additions would be necessary for the adequate discharge of the authors' self-imposed task.

KUCZYNSKI R. R. *Demographic Survey of the British Colonial Empire. Vol. I. West Africa.* pp. xi + 821. Issued under the auspices of the Royal Institute of International Affairs. 1948. London, New York, Toronto. Geoffrey Cumberlege, Oxford University Press. [73s.]

The first volume of this Survey deals with West Africa. It is packed with wealth of statistical and other documentary detail attractively presented and constructed throughout against a historical perspective.

The book is introduced with six sections dealing with the fundamentals, namely Census-taking, Total Population, Composition of Native Population, Composition of Non-Native Population, Birth and Death Registration, Native Fertility, Mortality and Population Growth, and Mortality of Europeans.

This sequence is followed in each of the main chapters, which deal respectively with Sierra Leone, Gambia, Gold Coast and Togoland, and Nigeria and the Cameroons.

Of special interest to medical reader will be the large amount of material dealt with under the arduous heading of mortality, which concerns the common infective and other diseases of the Tropics. The greater part of this material is taken from Annual Medical Reports of the Colonies and from similar sources but its assembly against this background gives it a new appeal. The Survey contains an immense amount of information which will be of value and interest to those who are concerned with West Africa and its welfare.

[No 6

SUMMARY OF RECENT ABSTRACTS*

V LEISHMANIASIS

VISCERAL LEISHMANIASIS

Epidemiology Aetiology Transmission

GIRAUD *et al* (p 984) review the incidence of kala azar in the Marseilles area, where 238 cases have been seen since 1923. It is found chiefly in children under 3 or 4 years of age, and the disease is also common in dogs. The authors suggest that transmission may be from dog to child by ticks rather than by sandflies, but this view is supported only by indirect evidence. RANQUE *et al* (p 883) also make the point that canine leishmaniasis is still found around Marseilles, and stress that early diagnosis can be made by gland puncture, before the formol reaction or the clinical features are diagnostic. Leishmaniae were found by DE AZEVEDO *et al* (p 985) in 6.5 per cent of 137 dogs examined in Lisbon. LUENGO ARROYO *et al* (p 163) report that infantile kala azar occurred in 13 provinces of Spain in 1946, they think that the squirrel may be a reservoir host, as well as the dog. BALLABRIGA (p 316) mentions 40 cases of infantile kala azar treated in Barcelona in three years.

BOSSELUT (p 775) describes disseminated leishmaniasis in a cat in Algiers, it has rarely been recorded before. The species of leishmania found is not named.

Kala azar is recorded from Sardinia (DORE, p 418), Palermo (MONDINI, p 418) and the Tuscan Archipelago (GUIDERI, p 418). BURGIO (p 507) reports an increase in the number of cases of infantile kala azar seen in Palermo in 1944-45.

SEN GUPTA (p 881) traces the history of kala azar in Calcutta since the special clinic was instituted in 1921. One part of the city is a highly endemic area. The number of cases seen rose above the general level in 1923-25 and again from 1944 to 1947, and the author thinks that the latter exacerbation was the result of the famine of 1943, and the presence of susceptible children born since the earlier epidemic wave. He thinks that the virulence of the parasite has been increased by passage through this enfeebled population. HEILIG and SACHDEV (p 246) suspect that kala azar may occur in Jaipur, India, which is outside the usually recognized endemic area. They admit that the diagnoses on which this suspicion is based are not conclusive.

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1948, v 45. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

The book is clearly and concisely written and very well produced. It is evidently based on wide personal experience but the authors claim that their manual takes count of recent advances in knowledge of the aetiology and treatment of tropical diseases can hardly be substantiated. One non-artery numerous for example new methods of malaria therapy need a bare mention and the yellow fever chapter is very inadequate.

Rapidity of progress in the domain of tropical medicine has been so great during the last ten years that the difficulties attendant upon the production of an up-to-date manual are almost insurmountable. The major part of this volume would appear to have been written several years ago. Very considerable additions would be necessary for the adequate discharge of the authors' self-imposed task.

Norman White

KUCZAKSKI R. R. *Demographic Survey of the British Colonial Empire. Vol. 1. West Africa.* pp. xvi + 821. Issued under the auspices of the Royal Institute of International Affairs. 1948. London, New York, Toronto. Geoffrey Cumberlege, Oxford University Press. [75s.]

The first volume of this Survey deals with West Africa. It is packed with wealth of statistical and other documentary detail attractively presented and constructed throughout against a historical perspective.

The book is introduced with seven sections dealing with the fundamental namely Census-taking, Total Population, Composition of Native Population, Composition of Non-Native Population, Birth and Death Registration, Native Fertility, Mortality and Population Growth, and Mortality of Europeans.

This sequence is followed in each of the main chapters which deal respectively with Sierra Leone, Gambia, Gold Coast and Togoland, and Nigeria and the Cameroons.

Of special interest to medical readers will be the large amount of material dealt with under the various headings of mortality which concern the common infective and other diseases of the Tropics. The greater part of this material is taken from Annual Medical Reports of the Colonies and from similar sources but its assembly against this background gives it renewed appeal. The Survey contains an immense amount of information which will be of value and interest to those who are concerned with West Africa and its welfare.

H. J. O. D. B. de-Graffney

endothelial cells tend to disappear, and the normal elements to increase RACHMILEWITZ *et al* (p 984) think that the cause of the anaemia of kala azar is increased destruction of red cells

The electrocardiogram shows no valid evidence of change characteristic of kala azar in children, GIVA and BINAGHI (p 1074) think that such changes as occur indicate myocardial affection due to a toxic factor or to the anaemia

SEN GUPTA *et al* (p 882) report 4 cases of pneumococcal meningitis in patients with kala azar

Treatment

ADAMS and SEATON (p 246) have treated 6 patients with kala azar by an intensive course of intravenous sodium antimonyl tartrate, lasting for only two days. The results were not so good as those obtained with stibosan, urea stibamine or the diamidines, but the course may have advantages if a longer period of treatment is not possible. In a communication relating to this paper, NAPIER (p 247) refers to the danger in treatment with sodium antimonyl tartrate, and suggests that for intensive treatment the benign pentavalent compounds should be chosen rather than this relatively toxic trivalent salt

AVERSA and CROSCA (p 507) did not find that iron added to the value of antimony in the treatment of infantile kala azar, in relation to the blood picture

CARNEVALE (p 419) found that there was a concomitant syphilitic infection in four cases of infantile kala azar, which resisted treatment with tartar emetic until the syphilis had been treated. Resistance to antimonials should raise the suspicion of syphilis

SWITH *et al* (p 985) have investigated in animals the tissue distribution of radioactive antimony inhaled as stibine

BURCHENAL *et al* (p 319) record a case of kala azar in which treatment with many antimonial and other drugs was ineffectual, and the patient was eventually cured by splenectomy. After this operation there was rapid improvement in the blood picture and in symptoms, the spleen was very large and contained a large infarct. The authors discuss the subject and the points which should be borne in mind when splenectomy is contemplated

ADLER *et al* (p 774) think that the Sudan strain of *L. donovani* behaves like *L. infantum* in response to treatment and should probably be classed as *L. infantum*. They found that propamidine and pentamidine have significantly less action *in vitro* on the flagellates of *L. infantum* than on those of *L. donovani*, but that the effect of stilbamidine is the same on both, though less than that of the other two compounds. In comment, however, LOURIE points out that when measured by a different technique the effect of stilbamidine is much the same as that of the other two drugs against flagellates of *L. donovani*, and suggests that this technique should be used to compare the response to stilbamidine of flagellates of *L. donovani* and *L. infantum*. The LD bodies were more sensitive than flagellates to each compound

COLLARD and HARGREAVES (p 320) report that in 22 of 24 patients in whom they used stilbamidine for the treatment of Mediterranean kala azar, there occurred late evidence of neuropathy which was serious. The symptoms were anaesthesia, paraesthesia or hyperaesthesia, usually of the face, scalp and neck, and the skin sometimes became dry and atrophic. No treatment had any effect but the condition remained at its maximum up to 18 months and then gradually improved. In an investigation of the toxic properties of solutions of stilbamidine exposed to sunlight FULTON (p 508) has investigated the constitution of photostilbamidine, the irradiation product of stilbamidine which apparently undergoes dimerization on exposure to sunlight. HENRY (p 775) thinks that the delayed toxic effects observed after administration of

FELTON and JOYNER (p. 775) show that the cotton rat is susceptible to infection with *L. donovani*. The disease progresses but is not fatal. BOLLEGER and BACKHOUS (p. 883) have transmitted *L. donovani* to the pouch young of 24 Australian possums (*Trichosurus vulpecula*) and one ring tailed possum (*Pseudocheirus lewinsoni*) and describe the lesions produced. It is evident that the first of these marsupials is highly susceptible and may be a suitable animal for investigation of the disease.

HAWKING (p. 503) has succeeded in growing *L. donovani* in tissue culture. SHIH LU CHANG (p. 774) has studied the biochemical activities in culture and respiration of three species of leishmania and *T. cruzi*. For details the original abstract may be consulted.

By agglutination complement fixation and precipitin test SHIH LU CHANG and NEGERSON (p. 590) have shown that culture forms of *L. donovani*, *L. brasiliensis*, *L. tropica* and *Trypanosoma cruzi* possess both species-specific and common antigens. GHOSH and GHOSH (p. 692) have investigated the complement-fixation and agglutination reactions of rabbits immunized with a living culture of *L. donovani*. Titres were high; there is apparently no distinction between H and O antigens.

ROMAN (p. 55) gives a list of *Phlebotomus* species caught in Tunisia. HARRIS and LEWIS (p. 163) note that *Phlebotomus longirostris* var. *orientalis* is the only one of the *P. major* group whose distribution is related to that of kala azar in the Sudan. Its occurrence is erratic and variable and this may have some bearing on the erratic and variable occurrence of kala azar. The authors discuss other species found including *P. papatasi* and they note that cracks in the soil and animal burrows, form a vast mass of subterranean resting places. It is not known whether these are also breeding places.

Tests Clinical Findings

HO *et al.* (p. 694) have compared spleen puncture, sternum puncture and liver puncture as diagnostic procedures in kala azar. Spleen puncture apparently gave the best results, closely followed by sternum puncture and the authors advise that both should be done to ensure accurate diagnosis. Liver puncture is considerably less useful. The pathological appearances in one fatal case of kala azar in which death followed spleen puncture are described by LEWIS (p. 697).

CARNEYALE (p. 507) describes a test in which the speed of penetration of HCl into serum gel (with Congo red) is measured; the speed is slightly increased in kala azar. TRINGLO (p. 695) has observed that when HCl is added to the serum of patients with kala azar, jellyfication takes place.

LEVY and YERGANI (p. 319) describe a case with an incubation period of 17 months.

MOST and LAVITTE (p. 317) describe the signs and symptoms of kala azar as they saw it in 39 American soldiers who contracted the disease in India or in the Mediterranean area. For detail the original abstract may be consulted, but they are not exceptional. In comment VARELA remarks that his impression of this paper is that it demonstrates how very standardized kala azar is in the adult whether acquired in India or the Mediterranean.

GATTO (p. 418) describes the splenogram in infantile kala azar and MORAVO (p. 418) a case in which kala azar seemed to be involved in the aetiology of the Banti syndrome.

CAPTWEI *et al.* (p. 693) discuss their work on the pancytopenia of kala azar as they studied it in China. Anaemia a constant and normochromic orthochromic type. Leucopenia an almost constant feature and platelets are reduced. The bone marrow always hyperplastic and a full description of the cell is given. During effective treatment the para-medullary reticulo-

endothelial cells tend to disappear, and the normal elements to increase RACHMILEWITZ *et al* (p 984) think that the cause of the anaemia of kala azar is increased destruction of red cells

The electrocardiogram shows no valid evidence of change characteristic of kala azar in children, GIVA and BINAGHI (p 1074) think that such changes as occur indicate myocardial affection due to a toxic factor or to the anaemia

SEN GUPTA *et al* (p 882) report 4 cases of pneumococcal meningitis in patients with kala azar

Treatment

ADAMS and SEATON (p 246) have treated 6 patients with kala azar by an intensive course of intravenous sodium antimonyl tartrate, lasting for only two days The results were not so good as those obtained with stibosan, urea stibamine or the diamidines, but the course may have advantages if a longer period of treatment is not possible In a communication relating to this paper, NAPIER (p 247) refers to the danger in treatment with sodium antimonyl tartrate, and suggests that for intensive treatment the benign pentavalent compounds should be chosen rather than this relatively toxic trivalent salt

AVERSA and CROSCA (p 507) did not find that iron added to the value of antimony in the treatment of infantile kala azar, in relation to the blood picture

CARNEVALE (p 419) found that there was a concomitant syphilitic infection in four cases of infantile kala azar, which resisted treatment with tartar emetic until the syphilis had been treated Resistance to antimonials should raise the suspicion of syphilis

SMITH *et al* (p 985) have investigated in animals the tissue distribution of radioactive antimony inhaled as stibine

BURCHENAL *et al* (p 319) record a case of kala azar in which treatment with many antimonial and other drugs was ineffectual, and the patient was eventually cured by splenectomy After this operation there was rapid improvement in the blood picture and in symptoms, the spleen was very large and contained a large infarct The authors discuss the subject and the points which should be borne in mind when splenectomy is contemplated

ADLER *et al* (p 774) think that the Sudan strain of *L. donovani* behaves like *L. infantum* in response to treatment, and should probably be classed as *L. infantum* They found that propamidine and pentamidine have significantly less action *in vitro* on the flagellates of *L. infantum* than on those of *L. donovani*, but that the effect of stilbamidine is the same on both, though less than that of the other two compounds In comment, however, LOURIE points out that when measured by a different technique the effect of stilbamidine is much the same as that of the other two drugs against flagellates of *L. donovani*, and suggests that this technique should be used to compare the response to stilbamidine of flagellates of *L. donovani* and *L. infantum* The LD bodies were more sensitive than flagellates to each compound

COLLARD and HARGREAVES (p 320) report that in 22 of 24 patients in whom they used stilbamidine for the treatment of Mediterranean kala azar, there occurred late evidence of neuropathy, which was serious The symptoms were anaesthesia, paraesthesia or hyperaesthesia, usually of the face, scalp and neck, and the skin sometimes became dry and atrophic No treatment had any effect, but the condition remained at its maximum up to 18 months and then gradually improved In an investigation of the toxic properties of solutions of stilbamidine exposed to sunlight, FULTON (p 508) has investigated the constitution of photostilbamidine, the irradiation product of stilbamidine, which apparently undergoes dimerization on exposure to sunlight HENRY (p 775) thinks that the delayed toxic effects observed after administration of

stilbamidine may be due to the formation of a monoamide in the body. He discusses the changes which may take place when stilbamidine is exposed to light.

The histological changes in chronic poisoning of animals with stilbamidine are recorded by SEAGER and CASTELLINOVO (p 164). There were degenerative changes chiefly in the liver and kidneys.

HARTON (p. 56) shows that stilbamidine is excreted largely in the form of a non fluorescent compound, since fluorimetric methods detect in the urine only one twentieth of the amount detected by colorimetric methods.

CUTANEOUS AND MUCO-CUTANEOUS LEISHMANIASIS

KATZENELLENBOGEN (p. 55) reports a new endemic form of oriental sore (of the dry type) in southern Palestine.

ANSARI (p. 184) has succeeded in infecting white mice by injection of culture forms of *L. tropica*. Intradermal, intraperitoneal and intratesticular injections were successful, but the last were most constantly so though there were refractory mice in each group. A local granuloma is formed, which eventually gives rise to systemic infection with lesion resembling those of kala azar.

Snow *et al.* (p. 695) note that cutaneous leishmaniasis is uncommon in the Panama Canal Zone and they report on 12 cases seen in the Gorgas Hospital since 1937. The lesions were all on exposed parts of the body and presented as ulcers with multiple small subcutaneous nodules along the regional lymphatics. Leishmaniasis was found in biopsy material from the ulcers. Treatment with various antimonials was successful.

GOLDMAN (p. 47) discusses the classification of American cutaneous leishmaniasis of which the special feature is involvement of mucous membranes either by direct extension from a cutaneous lesion or by metastasis. Clinical and parasitological diagnoses are always difficult—casual scraping of the lesion is useless.

MANGABEIRA-ALFENAZ (p. 321) describes in detail various forms of leishmanial nasal nodule as it occurs in American mucocutaneous leishmaniasis.

GUIMARÃES (p. 508) records (for the first time) that local infection (on the nose) of a hamster with *L. t. ashmeadi* led to a generalized spread of the infection.

PRASOŁ and ROTBERG (p. 694) report favourably on an intense short course of tartar emetic in the treatment of American cutaneous leishmaniasis.

HERRIG and FAIRCHILD (p. 834) used DDT as a residual spray in the control of sandflies in Peru, with success. They sprayed houses, cañitas in dry stone walls, etc., and rarely found sandflies in the sprayed places until several months later. The method seems to be successful in preventing the spread of leishmaniasis and bartonellosis.

MUNIZ and MEDINA (p. 776) describe a new species of *Leishmania* pathogenic for the guinea pig and TORRES *et al.* (p. 778) give an account of the lesions it provokes.

MALARIA

BOSCARDI, F & CORSI, C Considerazioni epidemiologiche sui malarici di una collettività di profughi in Roma, provenienti dalle provincie diverse del Lazio, negli anni 1945-1946 [Epidemiological Data concerning Malaria among a Group of Refugees in Rome coming from Various Provinces of Latium in 1945-1946] *Ann d'Igiene* 1948, Jan-Feb, v 58, No 1, 13-22, 4 figs & 1 map

In 1945 many thousands of refugees arrived in Rome fleeing from battle areas Of 7,225 that were under observation 3,551 came from one or other of the five provinces of Latium Of the latter, 408 were suffering from malaria, some of the sufferers coming from districts which had been free from endemic malaria till the destruction of war had caused a remarkable extension of infected territory Of 1,266 refugees from Latina 28.5 per cent were infected, of 406 from Frosinone 7.14 per cent., and of 1,848 from the Province of Rome 0.97 per cent There was no malaria among the small number of refugees coming from the Provinces of Rieti and Viterbo The intensely malarious area was confined to the whole of the Province of Latina, a small adjacent part of the Province of Rome and the southern third of the Province of Frosinone

Norman White

DELBOVE, P & CAPPONI, M Impaludation et prémunition en milieu cambodgien [Malaria Infestation and Premunition of Cambodians] *Bull Soc Path Exot* 1948, v 41, Nos 7/8, 474-8

Malaria has afflicted Cambodia since ancient times To it has been ascribed the disappearance of the Mon-Khmer civilization Today malaria is severely endemic or hyperendemic throughout the country, with the exception of areas bordering on the Mekong River and the Great Lakes Nevertheless the adult Cambodian is generally a robust person, capable of really hard manual labour, and appears to suffer little or nothing from his malaria infection But the observations recorded in this paper indicate that the Cambodian's noteworthy tolerance of malaria is not due to a state of premunition properly so called Spleen rates and parasite rates of adults are not very much lower than those of children and they are subject to well-marked seasonal variation In the rainy season, these rates approximate those that one would expect among a population devoid of premunition in a highly malarious region In the long dry season there is a marked reduction in the parasite rate, most marked among adults, but the spleen rates persist at a high level It would seem that exposure to infection throughout the year is necessary to the development of premunition such as is acquired by the Moïs in the high plateaux of Southern Indochina

NETO, J C de M F, TÔRRES, A L & PINTO, G F Estudo epidemiológico sobre a malária na localidade no Imbuí (Município de Niterói, Estado do Rio de Janeiro) e plano para o saneamento da região [Epidemiological Study of Malaria in Imbuí (Niterói District, State of Rio de Janeiro) with a Plan for the Sanitation of the Area] *Rev Hig e Saúde Pública* 1947, Oct-Dec, v 5, No 3, 1-38, 6 graphs & 23 figs

Imbuí lies 12 kilometres south of the city of Rio de Janeiro The area surveyed contains a civil population of 693 living in primitive conditions, mostly fisher folk Malaria and malnutrition are rife, tuberculosis is very prevalent There is also a Fort with a garrison strength of some 125 to 155, which is changed annually In 1945 there were 50 cases of malaria in the

garrison, and 68 cases in 1948. *P. m.* infections were most common; *P. malariae* was rare. The most prevalent anopheline was *A. farinivittatus*, the chief vector; a lagoon was the chief breeding place. *A. bellator* also occurs. bromeliads are plentiful in the district. Control measures include the construction of a dyke from the sea to a large lagoon; the resulting increase of salinity of the lagoon water should prohibit mosquito breeding.

GORDON R. M. & CREWE W. The Mechanisms by which Mosquitoes and Tsetse-Flies obtain their Blood-Meal, the Histology of the Lesions produced, and the Subsequent Reactions of the Mammalian Host together with some Observations on the Feeding of *Cixius* and *Cimex*. *Ann Trop Med & Parasit* 1945, Dec. v. 42, Nos. 3-4 334-58 2 graphs, 9 text figs. & 14 figs. on 4 pls. [44 refs.]

This study is not primarily concerned with clinical aspects of insect bites; it deals chiefly from a parasitological viewpoint with the local trauma and reactions at the site of the bite since it is the authors' opinion that these may be found to play an important, possibly essential, part in the transmission and subsequent development of certain insect-borne infections.

The paper is divided into Part I concerned with the bites of mosquitoes (*Aedes aegypti*, *Anopheles maculipennis* and *Culex molestus*) and Part II dealing with tsetse fly bites (*Glossina palpalis* or *G. morsitans*). Some notes are included on the bites of *Cixius* and *Cimex*.

Part I—The methods by which *Aedes aegypti* obtains blood from its host were described by GORDON and LUNDEN (this Bulletin 1940 v. 37 633) who showed that the tsetse is capable of distal flexure after deep insertion. It is capable of either penetrating a capillary, curving along its course and drawing blood directly from it or alternatively one or more capillaries are lacerated with a resultant haemorrhage into the inter-capillary spaces from which the mosquito then feeds ("pool-feeding"). Salivary secretion is injected into the tissues at intervals during the process of biting.

In non-sensitized animals and presumably in non-sensitized human beings, the only immediate effect of the bites of *Aedes aegypti* is the occurrence of slight haemorrhages. These persist for at least twenty-four hours. Agglutination of red blood corpuscles occurred only in bites of *A. maculipennis* which is known to contain an agglutinin in its salivary secretion (this Bulletin 1934 v. 21 783).

It is recognized (HICHT *Rev. Sanit. Assint. Soc. Caracas* 1943 8 391 and MELLANBY this Bulletin 1947 v. 44 740) that reaction to mosquito bites may consist of an immediate local reaction and a delayed papular reaction. The immediate reaction is often severe and attracts attention; the delayed reaction is generally less apparent and is frequently overlooked.

The immediate local reaction fails to appear in persons not previously bitten by a particular species of mosquito but after repeated irregular exposure to its bite a state of allergy is developed and the local reaction appears during or immediately after bite. This allergic response persists unless the host is exposed to regular and frequent bites in which case the reaction diminishes progressively in duration and intensity until the host is desensitized and ceases to react. Sensitization can be avoided if a person not previously bitten by a particular species of mosquito is exposed regularly and frequently to it. For example, no reaction occurred in a person exposed almost daily for 185 days to two or three *Aedes aegypti* bites. The causative substance is shown to exist in the salivary secretion of the mosquito. Sensitivity is highly specific; a person about equally sensitive to two species of mosquito was desensitized

to one (*Aedes aegypti*) and retained sensitivity to the other (*Culex molestus*). In the event of a person ceasing to be exposed regularly to bites the state of desensitization may be lost and the reaction reappear.

The *delayed papular reaction* appears within about twenty-four hours after the first exposure, or first few exposures, of a person unsensitized to the bite of *Aedes aegypti*. It may then persist for about 160 hours. Over a period of time its onset comes earlier and its duration and intensity are diminished. Loss of this reaction follows both regular and irregular exposure to bites. Its causation is attributed by the authors to a slow-acting toxin injected with the mosquito's salivary secretion and not to sensitization as in the case of the immediate reaction. The localised swelling of the delayed reaction is histologically shown to be due to the separation of collagen fibres by extravasated fluid from the lacerated capillaries, small haemorrhages are attributed to the action of the mouthparts at the time of biting.

It is suggested that the "immunity" of indigenous persons in the tropics to mosquito bites is not a racial characteristic but is due to their exposure to constant bites from birth.

Part II—The proboscis of the tsetse fly is capable, like that of the mosquito of distal flexure. Feeding from intercapillary haemorrhages ("pool-feeding") is considered to be the usual source of blood of the feeding fly. Such a haemorrhage increases during the first twenty-four hours, except in the case of bites by flies from which the salivary glands have been removed, and part of the blood may sink among the underlying muscle fibres, the blood is invaded—mostly by histiocytes—after forty-eight hours and, after seventy-two hours, the tissue is again normal. This uncomplicated resolution of the haemorrhage occurs in non-sensitized persons in whom, furthermore, no visible reaction can be detected on the occasion of their first, or first few, bites from tsetse fly. On the other hand in sensitized persons—and this state can be attained after as few as four or five bites—there is, presumably owing to leakage of fluid from damaged capillaries, extensive separation of collagen fibres and dilatation of vessels to form a weal. Severe swelling of adjacent parts occurs in highly sensitive persons. Removal of the fly's glands prevents the appearance of the weal in sensitive persons and it is, therefore, concluded that the substance responsible for the reaction is in the salivary secretion. It is probable, from general evidence, that desensitization follows continuous regular exposure to bites and that although sensitization is not localized, desensitization is most marked in the bitten area. This seems to apply both to tsetse and mosquito bites. The authors find no evidence in tsetse fly bites of a delayed action nor of the slow toxic poison which they consider to be responsible for it in mosquito bites.

Chrysops and *Cimex* bites also give rise to a subcutaneous haemorrhage and, in *Cimex*, distal flexure of the mouthparts in the skin is demonstrated. It seems then that "pool feeding" is a frequent event in blood-sucking insects, it is probably the rule in tsetse fly feeding, but capillary feeding is thought to be more usual in mosquitoes.

This paper is, in addition to its original matter a comprehensive collation and discussion of a widely scattered literature on the subject of insect bites, the interpretation of the host-reactions, the use of antigen for desensitization and the effects of drugs on bites. In this last connexion the anti-histamine drug benadryl, at 150 mgm daily for three days gave no appreciable change in the appearance of the immediate reaction in two persons highly sensitive to *Aedes aegypti* but the itching sensation was markedly diminished. There was however, some indication that a general reaction which follows injection of large amounts of salivary antigen into a highly sensitive person is reduced by the drug.

The plates consist of one photograph of the proboscis of a tsetse fly penetrating skin (skin section at $\times 200$) and 13 photographs of skin sectioned at different intervals after insect bites.

SEFULORI P & MESSA, A. Ciclo gonotrofico delle anofeline ibernanti in provincia di Venezia. [Gonotrophic Cycle of Anophelines hibernating in the Province of Venice.] *Riv di Malariologia*. 1948, Aug. v 27 No. 4 139-50 1 map.

The English summary appended to the paper is as follows —

The authors have observed that hibernation of *A. maculipennis* starts in the province of Venice at the end of October and continues during November. It is nearly complete by December and lasts the whole month of January. At the beginning of hibernation (November) the dissociation and gonotrophic disharmony may possibly explain primary malaria infections. The danger does not exist in December and January.

During the month of February *Anopheles* becomes active again and start their gonotrophic activity which in March is extended to 95% of the captured adults.

FARID M A. A Preliminary Note on an Unusual Breeding Place of *Anopheles gambiae* in Egypt. *J Roy Egyptian Med. Ass.* 1943 Apr., v 28 No. 4 123-8 2 figs.

After noting the measures taken to eradicate *Anopheles gambiae* from Egypt, the author records the finding of the larvae of this mosquito among the floating mats of the water plant *Potamogeton* in the river Nile. One such mat was 3-10 metres from the shore 5-7 metres wide and 500 metres long. Another mat was in water so deep that it could be reached only by boat. The necessity for the destruction of these *Potamogeton* mats is stressed, because pieces break off and float down the river taking the larvae with them.

H S Larson

MAURITIUS COLONY OF. Annual Report on the Medical and Health Department 1947 [RANKINE A., Director]. 48 pp. 1949 Port Louis J. E. Ed. Felix Govt. Printer [60 cents.]

In this Report (which will be reviewed separately) it is noted that during the course of a mosquito survey of the Savanne District of Mauritius in 1947 a specimen of *Anopheles maculipes* was found in November in the village of St. Martin. This is the first record of the finding of this species in Mauritius. It is added that a few days later in the same village another mosquito new to the island was discovered — this was a species of *Mansonioides*.

H J O'D Burke-Gaffney

LEESON H S. Anopheline Larvae collected in Arabia. *Am Trop Med & Parasit* 1948 Dec. v 42, Nos. 3-4 253-5 1 map.

A report on anopheline larvae collected in 1944 and in a footnote on anopheline adults taken between January 1947 and February 1948 in Arabia. The larval collections were made in the coastal area from Jubail to Khobar and at Hofuf and in the area of El Kharj about 50 and 200 miles inland, respectively and from parts of the Oman and Trucial Oman area at the entrance to the Persian Gulf. Adult records are restricted to the Jubail-Khobar area and to El Kharj.

In January in the Jubail-Khobar strip larvae of *A. stephensi* the most numerous species were encountered particularly in drain, wells and borrow

pits *A. fluviatilis* larvae occurred in shaded fresh-running water in drainage and irrigation canals and, at Saihat, in brackish wells. Other larvae recorded, in order of frequency, were *A. sergenti*, *pulcherrimus*, *multicolor* and *coustani*.

All these species were also found at Hoffuf in the larval stage with the addition of a few *A. hyrcanus* larvae and one specimen, accepted as *A. cinereus*, but in which it is noted that hair 13 of the ventral prothorax has three branches instead of six or seven as described for this species elsewhere. *A. stephensi* and *A. fluviatilis* larvae were common. No adults from this area are recorded in the 1947-48 collection.

In the El Kharij area, only *A. multicolor* larvae were observed in February despite a careful search for other species, it occurred in drains, irrigation canals, and wells. The adult records consist of *A. multicolor* and *A. stephensi*.

In most of the parts of Oman and Trucil Oman examined in March and April 1944, *A. culicifacies* was the only species found and bred chiefly in freshwater wells. A few larvae of *A. adenensis* and *A. stephensi*, however, were taken in this area. No adults are recorded from this region.

The paper concludes with a key to the fourth stage larvae of the species named above with the addition of *A. turkhudi*, *hispaniola*, *d'thali* and *superpictus* which might be expected to occur in this little known region.

D S Bertram

DE ZULUETA, J & BATES, M. Laboratory Experiments with Selection of Oviposition Site by *Anopheles darlingi*. *Amer J Hyg* 1948, Nov, v 48, No 3, 350-60, 4 figs [11 refs]

A study was made of the behaviour of the ovipositing female *Anopheles darlingi* obtained from a laboratory colony. The experimental methods are described in detail and are illustrated by photographs.

Some of the results reported here may mean that visual orientation is of importance in determining the selection of an oviposition site. There were two peaks of egg-laying activity, one after sundown and one after sunrise. Females usually laid their eggs while hovering a few centimetres above the water surface, though some did so while resting on the water or on the sides of the vessel. Upright obstacles, represented by inverted test tubes or glass rods, standing in the oviposition pans, and other objects which broke the water surface, repelled the mosquitoes, but when tubes or rods were stood around outside the pan they were attractive to them. A pan shaded by cardboard 35 centimetres above the water surface was attractive, but a sheet of glass in the same position had no effect, if the glass was lowered to 15 centimetres the pan was avoided.

These and other results indicate a need for further experiments on these lines with other anopheline species.

PURI, I M. The Distribution of Anopheline Mosquitoes in India, Pakistan, Ceylon and Burma. Part V. Additional Records, 1936-47. *Indian J Malariology* 1948, Mar-June v 2, Nos 1/2, 67-107 [48 refs]

DI, F J & DEL ROSARIO, F. The Occurrence of *Anopheles minimus flavirostris* (Ludlow) in the City of Manila. Reprinted from *Acta Med Philippina* 1948, Jan-Mar, v 4, No 3, 9 pp, 4 figs & 1 map on 3 pls.

This is the first record of *Anopheles minimus flavirostris** breeding in the city of Manila. It bred in two streams about a hundred yards from a populous area. The possibility that it may transmit malaria within the city is raised,

and the case of a 2-year-old child who may have contracted her infection of *P. falciparum* within the city limits is recorded. It is postulated that heavy losses in animals " (presumably caraboa) during the recent war may have caused a spread of the mosquito in the absence of sufficient animal host barriers or possibly this mosquito was missed in previous surveys.

Other species collected in the city area in the present survey were — *A. maculipes* *kyrcanus* *niger* *kyrcanus* *lestus* *fulvipes* *tricolor* *luteolus* and *s. pictus* *indefinitus*. The collections were made during four days in December and consist mainly of larvae some of which were bred out a few adults of the species marked were taken near the streams.

D S Bertram

Dr F J & Garz R. B. Sporozoites of *Plasmodium* *sp.* in *Anopheles* *margareti* and Oöcysts in *A. kochi*. Reprinted from *Acta Med Philippina*, 1948 Jan-Mar., v 4 No 3 5 pp., 3 figs. on 2 pls.

Following a report that *Anopheles minimus flavirostris* the generally accepted malaria vector in the Philippines was relatively rare in the highly malarious Tabla Valley a search was made for anopheline adults in the vegetation of stream banks. The following species were taken — *A. minimus flavirostris*, *margareti* *kochi* *tricolor* *subpictus* *indefinitus* *negus* *hirsutus* *maculipes* *kyrcanus* *niger* *kyrcanus* and *larbrosus*. Sporozoites were found in the glands of 1 specimen of *A. m. flavirostris* and ? of *m. negus* as oöcysts in 3 of the former in 1 of the latter species and in 1 female of *A. kochi*. The numbers of each of these species dissected was small, viz 54 52 and 15 respectively. From 1 to 8 dissections of the other species were negative.

It is not certain that the *Plasmodium* *sp.* was of human origin but since the species were collected from the same place and included infected *A. minimus flavirostris* the results are presented as presumptive evidence that *A. margareti* is a vector of human malaria in the Philippines.

D S Bertram

WALKER, A. J. The Teaching of Malaria Diagnosis. *Amer J Trop Med* 1948 Nov v 28 No 6 777-85 7 figs. 129 refs.

The author shows considerable disagreement with most previous teachers of malaria as set forth in their published work. Much of the paper is indeed, a criticism of present teaching of the diagnosis of malaria and with much of it many practising malarialogists will not agree. After discussing the well known difficulties for the inexperienced in preparing adequate thin blood preparation the author gives strong arguments in favour of the well made thick film many workers will perhaps wonder why these arguments have been considered necessary.

Among his conclusions the author proposes that well prepared thin blood smears showing representative stages of the parasite should be used solely to demonstrate the general erythrocytic cycle that species diagnosis is best taught by demonstrating the special behaviour of *P. falciparum* in the peripheral blood and thereafter by the manner of differentiation between malarial and non-malarial infections and that material for study should consist of actual thick blood films on the ground that preparations of them do not lend themselves to photography or pictures.

The author makes a number of startling statements the ground for which are difficult to discover. For example on p 778 he suggests explanation for some reason why the writers of otherwise excellent textbooks have not devoted themselves to a consideration of thick film findings or the subject did not lend itself to such treatment. Again on p 781 with reference to

Schüffner's dots, is the disconcerting observation "I have yet to find a student, intern or technician who can demonstrate it in their own preparations"

There are many other points with which an abstracter might disagree not the least of these is the statement at the close of the paper "I request the suppression of too familiar charts and colored plates as being largely responsible for the general inadequacy of the statistics on malaria in this country as well as the hopelessness of the situation of students in regions where malaria exists"

H J O'D Burke-Gaffney

KISSIN, M & ADLEMAN, R J Transient Urticaria in Malaria *Amer J Trop Med* 1948, Nov, v 28, No 6, 797-802. [28 refs]

Five cases of transient urticaria were seen by the authors among 75 cases of malaria which they observed in a general hospital in China. Of the 75 cases, 73 were infected with *P. vivax*, 1 with *P. falciparum*, and 1 was a mixed infection. There was considerable variation in the size of the weals, and the degree of itching present. The rash appeared with the rise in temperature, persisted during the peak, and subsided with defervescence. Only one of the patients gave any history of previous allergic disorder, he had had a single attack of urticaria 12 years previously.

In the authors' experience the first or subsequent rigor might come on without an eruption, but once urticaria appeared as a sign during a bout of malaria, the eruption usually recurred with each temperature rise. The urticaria developed before antimalarial therapy was begun, and could not therefore be ascribed to medication with quinine, quinacrine [mepacrine] or salicylates.

CERABONA, M Contributo allo studio del rapporto tra nefrite e malaria [Observations on the Relations between Nephritis and Malaria] *Riv di Malarologia* 1948, Aug, v 27, No 4, 151-8 [20 refs]

The English summary appended to the paper is as follows —

"The author summarizes the various theories on nephritis from malaria and gives his observations made on 1,457 patients. Among these he found 13 patients with heavy and 38 a slight renal dysfunction. He considers that it must be admitted that malaria acts as a direct cause on the pathogenesis of renal alteration, even if one has to bear in mind that a prior renal weakness may exist in these individuals."

RADIAN, I Paludisme et leucémie myéloïde [Malaria and Myeloid Leukaemia] *Riv di Malarologia* 1948 Oct, v 27, No 5, 185-90, 2 figs

The English summary appended to the paper is as follows —

"A malaria patient (T M) with considerable hepatic splenomegaly and a haematological report of the myeloid leukaemia type was cured in two months by a treatment of quinine, primaquin and efedrin intravenous."

"The author discusses the relation between malaria and myeloid leukaemia and he points out the importance of malaria in the affections of the endothelial reticulum and of the bone-marrow."

FERRARI A. A dosagem dos sais de quinina na urina. Seu valor na clinica. Novos e velhos rumos na profilaxia. [Estimation of the Salts of Quinine in the Urine. New and Old Methods at Prophylaxis.] *Brazil-Medico* 1948, Nov 20 & 27 v. 62, Nos. 47/48 404-8.

"A dose of quinine acts more effectively the greater its dilution" because it then more readily penetrates to the capillaries and the reticulo-endothelial system in the organs where the parasites are hidden.

Determination of quinine in the urine is made by the Giemsa iodide-sublimate method. By this, freshly prepared solution of bichloride of mercury (1.8 per cent. in distilled water) is added just before use to an equal quantity of 20 per cent. potassium iodide. The urine is boiled and filtered and the reagent added. A blue disk forms at the junction if quinine is present and the rapidity of its appearance indicates the content of quinine. If within a minute 1/25,000 in two minutes 1/30,000 in three minutes 1/40,000 in five minutes 1/50,000. In a healthy person 0.5 gm. quinine per os will be evidenced in the urine in 15 minutes and elimination goes on for 4 hours. Slow elimination lasting more than 24 hours, is a bad sign, indicating circulatory stasis.

Some persons exhibit an intolerance to quinine and complain of tinnitus and vertigo but a dose of 0.5 gm. with 5 cgm. of extract of *Cinchona racemosa* taken in a capsule at 5 a.m. followed an hour later by a cup of coffee and a stay in bed for two hours proved quite satisfactory in the author's experience. A single dose each morning (for how long?) resulted in disappearance of the parasite. The author concludes that at this hour of the morning sporogony is taking place and the drug acts directly on the parasites in the blood. During the night the rosettes divide up and the schizonts dispersed in the plasma are attacked immediately by the quinine.

In subtertian infection the intravenous route is to be preferred the contents of an ampoule diluted in 100 cc. physiological saline gave admirable results in hospital practice. The collaboration of the reticulo-endothelial system in destruction of the parasites he maintain is facilitated by proper dilution and penetration of the quinine into the capillary network.

MULLICK, K. L. B & GUPTA, J. C. Further Observations on Parenteral Paludrine Hydrochloride in Malarial Fever. *Indian Med. Gaz.* 1948 Oct., v. 83 No. 10 488-9

This is a report of the treatment of 191 patients suffering from malaria with intra-venous injections of paludrine. The patients were employees of the Ludlow Jute Mills, Chengal. The diagnoses were based on clinical symptoms. In this locality 85 per cent. of malaria infection are said to be due to *P. vivax*. Paludrine tablet were dissolved in normal saline solution one tablet 0.1 gm. in 5 ml. After sedimentation the clear supernatant fluid was siphoned off and autoclaved. Twenty ml. (4 tablet) were usually injected some patients received 30 or 35 ml. at an injection. Fever was suppressed in 75 per cent. of

the cases within the 12 hours following the injection. The dose of 20 ml was as effective as higher doses. There were no toxic symptoms. After the patients had become afebrile, tablets were given by mouth to complete a course of 21 tablets in all.

CANET, J. Premiers essais de traitement curatif du paludisme aigu en Cochinchine. Par un nouveau médicament synthétique la Nivaquine C ou 3 038 R P [First Trials of a New Synthetic Drug, Nivaquine C or 3,038 R P, in the Treatment of Acute Malaria in Cochinchina] *Bull Soc Path Exot* 1948, v 41, Nos 7/8, 527-32

These observations were made in the Quanloi Hospital, Honquan. Twenty patients were treated, 2 Europeans and 18 indigenous agricultural workers who had come originally from Tonking but who had all been long employed on rubber estates in this hyperendemic malarious region. Most of the patients had marked splenic enlargement. All had been admitted to hospital with high fever and parasitaemia, 18 *P. falciparum*, 2 *P. vivax*. The drug was given in tablet form each containing 0.1 gm of the base. Fourteen of the patients received 3 tablets a day, two patients 4 tablets a day, and four 5 tablets a day. Fever ceased in the majority of the cases on the second or third day, parasites disappeared on the third or fourth day. Schizonts of both *P. falciparum* and *P. vivax* were equally susceptible to the action of the drug, but the gametocytes of *P. falciparum* were unaffected. A daily dose of 0.30 gm is adequate and a 5- or 6-day course of treatment is sufficient for an attack of average intensity. No symptoms of drug intolerance were ever noted. Nivaquine C is as effective as quinacrine and appears to act more rapidly. It should be of value for mass prophylaxis [see also this *Bulletin*, 1949, v 46, 15].

SOHIER, R, GREGOIRE, J & RANC, A. Traitement du paludisme à *Pl. vivax* par le dichlorhydrate de méthyl 3 (diéthyl amino-pentyl) amino-4-chloro-7-quinoléine (3038 R P ou Nivaquine C) et le sulfate neutre de (diéthyl-amino-pentyl) amino-4-chloro-7-quinoléine (3377 R P ou Nivaquine B) [Treatment of *P. vivax* Malaria with Nivaquine C and Nivaquine B] *Bull Soc Path Exot* 1948, v 41, Nos 7/8, 482-5

The 48 patients with *P. vivax* malaria who were treated with either Nivaquine C or B had mostly returned from Indochina where they had suffered from previous attacks. Both drugs were very effective in arresting fever and other symptoms. The dose of 0.5 gm a day for five days was well tolerated. Splenomegaly was notably reduced in 45 per cent of cases during this five-day treatment. Of 21 patients who were kept under observation for periods of from 2 to 7 months 4 relapsed.

SCHNEIDER, J & CARUANA, M. Essais de traitement curatif du paludisme par la sulfaméthylidiazine (Sumédine) [Treatment of Malaria with Sulphamethyldiazine] *Bull Soc Path Exot* 1948, v 41, Nos 7/8, 478-81

This reports the treatment of 14 patients suffering from malaria with sulphamethyldiazine. The dose for adults given was generally 3 or 4 gm a day for 4 days or more. In 4 of 6 patients with *P. falciparum* infections satisfactory results were obtained. In 6 of 8 patients with *P. vivax* the treatment was without effect. As an antimalarial drug sulphamethyldiazine is in every way inferior to the usual remedies.

MADINAVEITIA J. & RAVENTÓS J. Antimalarial Compounds as Antagonists of Adenosine. *Brit. J. Pharmacol. & Chemotherapy* 1949 Mar. v. 4 No. 1 81-92 4 figs. 76 refs.]

Antimalarial compounds antagonize the action of adenosine on the guinea pig heart and on the hen caecum.

A parallelism between the antimalarial activity and the power to antagonize adenosine has been demonstrated in most series of compounds examined.

In heart lung preparations it has been found that unlike the other antimalarials tested paludrine does not antagonize the action of adenosine. However the blood of paludrine-treated guinea pigs did antagonize this action. This is taken as evidence that paludrine is metabolized to another compound with different pharmacological properties.

The considerations which led to the testing of antimalarials as antagonists of adenosine are discussed.

LINDSKA, J. P. & MORTON F. A. Tests of the Permeability of Fabrics to Biting by Mosquitoes. *J. Economic Entomol.* 1948 Oct. v. 41 No. 3 783-91

Laboratory and field investigations were made at Orlando Florida, on the permeability to mosquito bites of cloths of different weaves of washed and unwashed fabrics of several styles of gloves of certain highly permeable fabrics when lined with various nettings of tangle suit made of different materials and of different types of flying suit.

The mosquitoes used in the laboratory tests were *Aedes aegypti* and *Anopheles quadrimaculatus*. A mosquito cage was specially designed to fit on the thigh above the knee for some of the tests for others an arm cage was used. In testing the suits in the field, the salt-marsh mosquito *Aedes triseriatus* was available in large numbers.

The results are summarized in six tables and show that of fifty-six fabrics tested, twenty-one of them allowed fewer than five per cent. of the mosquitoes to penetrate nine being practically impervious & only one per cent. of the mosquitoes succeeded in biting through them. A number of these test were confirmed in the field, the best materials being Bird cloth nylon filled poplin Jo cloth bea nylon and one style of cotton twill. Suits made of these materials provided good protection against mosquito bites. Washing of the fabrics had no significant difference to their permeability.

Mosquito-biting through highly permeable fabrics was eliminated or reduced when coarsely woven, open-mesh netting was worn underneath and in some cases gave better protection than some of the most resistant fabrics when worn alone.

Vol 46, No 6]

LEWIS, D J The Extermination of *Anopheles gambiae* in the Wadi Halfa Area
Trans Roy Soc Trop Med & Hyg 1949, Jan, v 42, No 4, 393-402,
 4 figs & 1 map [17 refs]

This paper should be read together with that by SHOUSHA [this *Bulletin*, 1949, v 46, 438] on the eradication of *Anopheles gambiae* from Egypt, as it completes the story of the disappearance of that mosquito from its northernmost extension and adds considerably to the discussion of how it came to travel so far

At the end of the Egyptian scheme a similar campaign was carried out in the neighbouring part of the Sudan In the winter of 1945-46 *A. gambiae* was eradicated from the 90-kilometre stretch of the Nile Valley between Faras (a border town at 22° 22'N) and Saras (21° 36'N) by a campaign based on hand distribution of 1 per cent paris green mixture to all potential breeding places Work was simple, rapidly effective, and undertaken by a staff of 17 men Proof of eradication is given by the fact that there has been no reappearance in 21 months since most larvicidal work was abandoned, during the last 13 of which it has been entirely abandoned and conditions have been unusually favourable for breeding

The work was intended mainly to provide a barrier to future invasions of Egypt by *A. gambiae* as it brings eradication back to a natural barrier of a long stretch of valley where there are few opportunities for breeding The author considers that this mosquito is native to the whole Nile Valley in the Sudan and perhaps to a part of Egypt, and claims the work as the first instance of the extermination of this species in an area of the Ethiopian zoogeographical region where it has occurred for many years

[This claim does not rest on quite secure ground as the evidence for the natural distribution of *A. gambiae* is circumstantial, and both the extent and the means of its extension are conjectural In 1938 it was not recorded north of Merowe (18° 29'N) In 1941 it was found at Wadi Halfa (21° 53'N) and in 1942 up to Assiut (27° 0'N) in Egypt There have been several records of malaria epidemics before this time within these limits So far as the Sudan is concerned the argument is that *A. gambiae* has long been present throughout the whole length of the Nile Valley in that country, but had not been reported because it had not been sought, most of the country being desert and many parts of the valley quite inaccessible However, past epidemics show its previous presence as there are no other effective carriers But *A. multicolor* is recorded as occurring So far as Egypt is concerned, the argument is that invasion is recent, importation being by boats, and past epidemics are attributable to favourable breeding conditions for other species such as *A. multicolor* The matter is one of considerable interest and cannot be considered settled]

BRISOU, J, CASTET, A & AUTHEMAN, R Expérimentation d'un nouveau produit antilarvaire [Experiments with a New Anti-Larval Preparation]
Bull Soc Path Exot 1948, v 41, Nos 7/8, 485-7

"Gyron" is a yellow powder consisting of very finely ground cork in which is incorporated 5 per cent DDT The preparation floats on the surface of water for about three weeks and collects among the grass and rushes along the borders of marshes, favoured places for mosquito breeding Laboratory tests and practical experiments on vast areas of marsh have shown it to be an excellent larvicide, in doses less than 2 gm per square meter Pupae are not destroyed, but the imago dies soon after its emergence Aeroplane dusting with this material from a low-flying Tiger Moth has been used over extensive swamps near Ferryville, Tunisia In Tunisia larvae begin to reappear eighteen days

after treatment which should then be repeated. Water thus treated is toxic neither for domestic animals, nor for fish, amphibia nor the microfauna of ponds and marsh. This larvicidal measure together with DDT spraying of houses has resulted in almost the total disappearance of mosquitoes from the areas treated.

MALAYAN UNIOS. Annual Report of the Malaria Advisory Board for the Year 1947 (including also 1946 and 1948) [MACGREGOR, R. B., Chairman]. 24 pp. 6 charts. 1948. Kuala Lumpur Govt. Press. [1s or 2s. 4d.]

The Board was first formed in 1911 with the object of co-ordinating the activities of estate owners, Government and private individuals, and took a large part in shaping the progress of malaria control in Malaya until its dissolution in 1941. It was reconstituted at the end of 1945 and has resumed its previous functions. This report briefly reviews the changes in the malaria situation during and since the Japanese occupation.

There was a great increase in malaria in 1942 and 1943 followed by an ostensible decrease in 1944 probably because the people saw the futility of attending hospitals where no drugs were obtainable. There has been a marked decrease since the end of the war partly owing to the fact that 1947 was a naturally healthy year but equally to the re-institution of control measures, the efficacy of which is now being reconsidered. The relative value of the various new methods of control is not yet clear. The one method which has been subjected to adequate trial is the use of proguanil (paludrine) and SN 7618 [chloroquine] with the aid of a grant from United Kingdom funds. A dose of 100 mgm. proguanil once a week has not been found effective but doses of 200 to 250 mgm. once a week have given effective suppression in most people with break throughs confined to children, and there has been no recorded failure of 300 mgm. once a week. A single weekly dose of 250 mgm. SN 7618 has about the same value and one weekly dose of 300 mgm. mepacrine compares in efficacy with 100 mgm. proguanil. Used therapeutically a single dose of 300 mgm. proguanil effects a clinical cure in *Plasmodium vivax* and *P. malariae* infections and in moderate infections with *P. falciparum*. A course of 300 mgm. daily for five days cures all types except those pernicious *P. falciparum* infections which require parenteral treatment. Used in this way proguanil is comparable with mepacrine.

Preliminary experiments have been carried out with DDT and Gammaxene as residual insecticides with promising but not yet convincing results. The nature of the breeding places in which *Anopheles maculatus* larvae occur makes it unlikely that much benefit can be derived from the larvicidal properties of these insecticides though their possibilities are being explored.

[The Board took a pioneer part in fostering malaria control for thirty years before the recent war. Its successful reconstitution will be welcomed by all interested in the subject.]

REID, J. A. DDT — A Review of its Possibilities for Public Health Work in Malaya. *M. I. J. Malaya* 1948, Dec. 3 No. 2, 105-27 [80 refs.]

MCCAULEY, R. H., JR. FAY, R. W. SIMMONS, S. W. A Comparison of the Residual Effectiveness of certain Insecticides against *Anopheles quadrimaculatus* Linn. *J. National Malaria Soc.* 1948 Dec., 7 No. 4, 291-8

The residual effectiveness of three insecticides, DDD, Chlordane and chlorinated camphene was compared with DDT. The following spray combinations were used —

- (1) 5 per cent DDT-xylene emulsion
- (2) 5 per cent DDT suspension from 90 per cent DDT water-wettable powder
- (3) 5 per cent DDT suspension from 50 per cent DDT water-wettable powder
- (4) 5 per cent DDD (dichlor-diphenyl-dichlorethane)-xylene emulsion
- (5) 5 per cent Chlordane-xylene emulsion
- (6) 5 per cent Chlordane-kerosene emulsion
- (7) 5 per cent chlorinated camphene-xylene emulsion
- (8) 5 per cent chlorinated camphene suspension from 25 per cent chlorinated camphene water-wettable powder

Laboratory-bred *Anopheles quadrimaculatus* 3-4 days old were set free in rooms, the walls and ceilings of which had been sprayed with 200 mgm /sq ft of insecticide, and the rate of knockdown was recorded. Regular tests were made from two weeks after spraying up to seven months.

DDT was shown to be more effective than the other insecticides. Tests in which 5 per cent DDT xylene emulsion or DDT suspension from 90 per cent water-wettable powder were used gave similar results, but the DDT suspension from 50 per cent water-wettable powder was less effective both in knockdown and residual action. It is suggested that this difference is due to a masking effect by inert ingredients.

Chlordane was as effective as DDT during the first three months, but thereafter its effect was not so great. Chlordane-kerosene emulsion gave a more rapid initial knockdown than chlordane-xylene emulsion.

DDD gave a slow rate of knockdown and a lower kill after four hours than DDT or chlordane, but it was more effective than chlorinated camphene which was found to have comparatively little residual effect. *C M Harrison*

QUARTERMAN, K D Some Factors Influencing the Residual Effectiveness of DDT and Chlordane in Anopheline Mosquito Control *J National Malaria Soc* 1948, Dec, v 7, No 4, 300-306

The factors examined were —

- (1) dosage,
- (2) retreatment of surfaces,
- (3) the effect of furniture in treated rooms

(1) The experiments were carried out in houses of concrete block construction. Previously untreated rooms of uniform size were sprayed with xylene-Triton-X-155 emulsions of DDT or chlordane at the rates of 200, 400, 800 mgm /sq ft. The knockdown of insectary-reared *Anopheles quadrimaculatus* released into these rooms was recorded at intervals of 30 minutes over a period of 4 hours. Test releases of mosquitoes were made every 1½ months over a period of 6 months.

There was no striking difference in the results with different dosages of DDT, but DDT applied at 200 mgm /sq ft was superior to chlordane in its residual effect. A dosage of 800 mgm /sq ft of chlordane when freshly applied was more effective than the same dosage of DDT. The author suggests that this is due to the strong fumigant action of chlordane.

(2) The effect of re-treatment was tested by applying 200 mgm /sq ft of DDT or chlordane to a surface which had received the same treatment 3 months previously. Knockdown was achieved more rapidly than with a single treatment but there was little difference in the results with re-treatment at 200 mgm /sq ft and a single treatment of 400 or 800 mgm /sq ft.

Rooms treated in 1946 with 200 mgm./sq. ft. of DDT or chlordane were re-treated in 1947 with 50 100 200 or 400 mgm. insecticide per sq. ft. The toxicity was restored approximately to the original value but there was no cumulative effect.

(3) A higher percentage knockdown was obtained in treated rooms without furniture than in rooms with either treated or untreated furniture. Rooms with furniture treated at 200 mgm./sq. ft. proved more effective than rooms with untreated furniture or furniture treated at any other rate.

DUNN I N. Hypersensitivity to Simian Malaria. *J. National Malaria Soc.* 1948, Dec. v 7 No. 4 285-74 [12 refs.]

This paper represents an attempt to demonstrate hypersensitivity in monkeys, infected with simian malaria, to various artificially produced malarial antigens. The monkeys used belonged to the species *Macaca mulatta* (spelt *Macaca*) and comprised 26 normal monkeys, 5 infected with *Plasmodium cynomolgi* and 16 infected with *P. knowlesi*.

Five antigens prepared from *P. knowlesi* were used. The basis of four of these was a mass of dried parasites obtained by haemolyzing the red cells of a parasitized monkey with distilled water repeatedly washing the parasites in the same and drying them in a vacuum.

Antigen I was prepared by powdering the dried parasites and making a 1 per cent. suspension in distilled water.

Antigen II was an extract of the dried parasites made by exposing 1 part to 100 parts of distilled water for one hour at room temperature and using the supernatant fluid.

Antigen III was a similar extract used after keeping the mixture in a refrigerator for 24 hours.

Antigen IV was made by extracting one part of dried parasites with 40 parts of Tyrode's solution followed by repeated freezing in dry ice and alcohol and thawing.

Antigen V was prepared by dissolving the mass of wet parasites in 0.1 N NaOH (1 gm. of parasites to 25 cc.) and neutralizing the solution with dilute phosphoric acid to bring the pH to about 8.0.

The control antigen was a 1 in 100 extract in distilled water of haemolyzed erythrocytes from normal monkeys.

In the case of *P. gallinaceum* Antigen I was the Malarial Antigen (Dried) of the Lederle Laboratories. A 1 in 100 suspension was used in distilled water.

Antigen II was a 1 in 100 extract in distilled water of the dried antigen kept at room temperature for 1 hour the supernatant fluid being used after settlement. The control antigen was a 1 in 100 suspension in distilled water of the dried material obtained from haemolyzed blood of normal chickens.

In testing these antigens, 0.1 cc. was inoculated intracutaneously. Readings were made at intervals of $\frac{1}{2}$ 24 48 and 72 hours after inoculation. In all cases the maximum response was obtained between 24 and 48 hours. The most significant results were obtained with *P. knowlesi* Antigen I.

Twenty-six normal monkeys showed a skin reaction averaging 3.7 mm. in diameter and never more than 5 mm.

In tests on 5 monkeys infected with *P. cynomolgi* one gave a reaction of 8 mm. in diameter two gave 7 mm. and two 5 mm. the reaction diminishing with the time which elapsed after the date of infection. The result was said to be statistically highly significant. [Whether this assumption is justifiable

on such small numbers is debatable, especially where the measurements between the normal upper limit of 5 mm and the maximum limit in infected animals of 8 mm showed a difference of 3 mm only]

The tests done on monkeys infected with *P knowlesi* were even less convincing, although here the species homologous to the antigen was being tested. In the case of these tests, on a total of 41 monkeys tested, the mean diameter of the reactions never reached 6 mm. The results obtained with the remaining *P knowlesi* antigens are detailed in tables. In all these the numbers of test animals are small and the results even less convincing.

The results with *P gallinaceum* antigen are also given in tables, but show little significance. Attempts to enhance the sensitization of infected animals by the use of various adjuvants were unsuccessful, as were attempts to demonstrate sensitization of macrophages *in vitro*.

[The general results of this work are not easy to evaluate. The small numbers of test animals used has been remarked upon and no indication is given of the means used for measurement of the reactions. This is important where fractions of a millimetre are given. The small margin between the diameters of the reaction in normal and test animals where the greatest reaction in the latter is only 8 millimetres and the normal may be as high as 5, obviously leaves many loopholes for error both in making measurements and in drawing inferences from them.]

H E Shortt

HARRIS, A & REIDEL, L M Evaluation of the Complement Fixation Test for Malaria *Amer J Trop Med* 1948, Nov, v 28, No 6, 787-95

The title is a little misleading as the paper is an account of complement fixation tests in malaria carried out by the authors themselves rather than an evaluation of the test in the light of previous work on the subject.

Merthiolated serum from sporozoite-infected donors, supposedly normal serum from students and serum from donors suffering from tuberculosis or syphilis, were the materials used in the tests. The Kolmer complement fixation test was employed, the antigens used being dehydrated corpuscle masses from monkeys infected with *Plasmodium knowlesi* and chickens with *P gallinaceum*.

As the functioning of the test is largely dependent on the potency of the antigen, the relative efficiency of these two antigens was first tested. Two *gallinaceum* and two *knowlesi* antigens were tested on 629 sera from sporozoite-infected donors, while human, monkey and chicken red cell stromata were used as control antigens.

The results showed extreme variability not only between the different antigens but between different lots of the same type of antigen. Thus, the same serum might give a strongly positive reaction and a strongly negative reaction with different antigens and there were other equally disconcerting results. In these tests, the *gallinaceum* antigens were decidedly more sensitive than the *knowlesi* antigens.

In another series of tests on 224 sera from the same series, the *gallinaceum* antigens again showed a higher proportion of positive results than the *knowlesi* antigens while in a third series of 31 similar sera, this result was reversed and a *knowlesi* antigen gave the higher number of positive reactions. The lower dilutions of antigen gave the greater number of positive reactions.

When the results of complement fixation tests were compared with the results of examination for parasites in the blood, equivocal results were obtained. Thus, the presence of malaria parasites in the blood was associated with both negative and positive complement fixation tests.

The specificity of the complement fixation test was next tested on 961 bloods from supposedly non-malarial donors, with both *gallinaceum* and *knowlesi*

antigens. The results went to show that less than 1 per cent. of false positive results was obtained so that the test could be regarded as highly specific so far as the positive results were concerned. Further evidence to this effect was obtained with sera from tuberculous and syphilitic patients.

The general conclusions to be drawn from the investigation are the necessity for the production of a standard antigen of constant potency, the fact that *gallinaceum* antigen appears to be the more reliable as well as the more specific antigen and the fact that the complement fixation test in its present form is no substitute for the finding of malarial parasites in blood films as a means of diagnosis.

BLACKWATER FEVER

JONCHERE H. AUFFRET C. & RAOULT A. Un nouveau cas d'anurie prolongée au cours d'une fièvre bilieuse hémoglobino-urique [A Case of Prolonged Anuria during Blackwater Fever] *Bull. M&I de l'Afrique Occidentale* *Ann. pédiat.* 1947 v. 4 No. 4 403-13

A long account is given of the clinical and pathological findings in a case of haemoglobinuria occurring in a European patient employed for 25 years in French West Africa and with a long history of chronic malaria. The haemoglobinuria appeared eight days after a heavy course of sulphathiazole treatment for chronic urethral discharge. A diagnosis of blackwater fever was made. The patient was oliguric from the beginning and rapidly became anuric. He died after a blood transfusion on the sixteenth day of his illness. Three days before death 432 grammes of urine containing traces of sulphobamide were removed by catheter. The following day he passed 1 100 cc. of urine which had a low urea concentration and contained traces of blood pigments, many casts and some blood cells. Vigorous treatment was administered which included intralumbar infiltration with novocaine, intravenous novocaine and intensive intravenous vitamin C dosage. (The vitamin was given because of its antihistamine activity in high dosage.)

Autopsy was performed immediately after death and the lesions of the organs including the kidneys and liver are discussed. The renal lesion was regarded as a toxic-infectious nephritis with extreme epithelial damage and heavy deposits of haemoglobin-pigmented material in the lumina of the tubules. There was considerable inflammatory infiltration. Crystals resembling those of sulphathiazole were also present in the tubules. In the liver the centrilobular veins and attendant capillaries were dilated and engorged and there was fatty degeneration in the cells of the centrilobular region. The Kupffer cells contained malarial pigment and there was a great deal of haemosiderin in the hepatic cells.

The authors suggest that the high dosage of sulphobamide might have influenced the development of lysis in the patient already heavily infected with malaria.

B. G. MARGRAH

CARAYON A. Les formes anuriques de la fièvre bilieuse hémoglobino-urique. Bases cliniques, anatomo-pathologiques et physiopathologiques du traitement. A propos de quatre cas personnels. [Anuria in Blackwater Fever. Clinical, Anatomical and Physiological Basis of Treatment in Four Cases.] *M&I Trop. Marcellina* 1948 July-Aug. Sept.-Oct. 8 No. 4 432-50

In three years at Conakry the author observed 15 anuric cases of blackwater fever four of which were treated by surgical interference including

decapsulation of the kidneys and infiltration of the renal pedicles with novocaine. The six anuric cases occurred in a total of 25 European cases, of which six others were polyuric. Other cases of blackwater fever, details of which are not discussed, were seen in Africans and in Lebanese. All European cases occurred in patients over the age of 30 and were associated with malaria treated with quinine.

The four cases which were treated surgically are dealt with fully, and detailed notes are given. These cases were all oliguric from the first appearance of blackwater. Anuria, defined as the passage of less than 50 cc of urine in 24 hours, developed within two days in all of them. Blood non-protein nitrogen (NPN) was high by the time of development of anuria. Another constant feature was the low urea concentration in the urine. Oliguria occurring early, accompanied by a reduction in urinary nitrogen and a rising blood NPN indicated increasing renal damage, which was concomitant with the haemoglobinuria and signs of liver failure. The author regards these cases as examples of the hepato renal syndrome.

Apparently autopsies were not performed but at operation in two cases the kidneys were found to be enlarged, firm and congested.

There is a long and interesting general discussion on the pathogenesis of renal failure in blackwater fever. The mechanical blockage theory is discussed and the conclusion is reached that it cannot explain the appearance of anuria. Other possible mechanisms are considered.

The author concludes that there are two predominant factors concerned in the pathogenesis of the renal damage, their relative importance depending on the circumstances of the individual case. The first of these factors is toxic-infectious and results from the malarial infection, it produces renal changes often associated with the hepato-renal syndrome. The other factor is tissue anoxia. Its importance is variable and depends upon the two elements which make it up, viz, (a) anaemia, which is more or less intense and dependent upon the malarial infection and haemolysis, and (b) vasomotor disturbances in which the intrarenal capillary pressure is affected. The author considers that the rôle of tissue anoxia in blackwater fever anuria has been over-estimated by Anglo-Saxon authors, possibly because of its importance in post-transfusional and crush syndrome anuria, where the appearance of shock is of more importance than in blackwater fever. In the four cases described by the author, shock was absent. In these cases he regards anaemia as being the more important in the production of tissue anoxia, since malarial anaemia presumably preceded that of the blackwater fever. He believes that this explains the inconstant effect on blackwater fever anuria of the surgical therapeutic measures described, measures which are more effective in crush syndrome and post-transfusional anuria, in which the vasomotor element is more obvious. No evidence of increased intrarenal pressure was found in his cases.

Theoretically, treatment of the individual case would depend upon the importance or otherwise of the vasomotor factor. If this were considerable, infiltration of the renal pedicles and decapsulation of the kidneys would probably produce good diuresis. Where tubular epithelial lesions were severe, the relief of the vasomotor effect by infiltration and decapsulation would restore diuresis but the urine would be poorly concentrated. Where severe tubular lesions and pronounced vasomotor states co-existed and operation was performed late, the results would be unsatisfactory.

There is a detailed discussion of the treatment of anuric cases in general. The author points out that it may be dangerous to attempt intensive alkali therapy and suggests that the anaemia which in his view is the main cause of tissue anoxia, should be treated with liver extract and transfusion. Repeated inhalation of oxygen may also help in attempting to control tissue anoxia.

Malaria should be treated and antimalarial drug given parenterally in the first instance. In the treatment of anuria he advises against the use of diuretics. He recommends injections of plasma and physiological saline in moderate doses. Hypertonic serum saline may be dangerous in the anuric period. Intravenous injection of novocaine which has given very successful results sometimes in anuria produced by sulphonamides may be tried but the author prefers infiltration of the renal pedicles with novocaine with the object of releasing sympathetic vaso-constrictor activity which may be responsible for the tissue anoxia. The technique of various surgical procedures is briefly described.

[This paper should be read in the original by those interested in the subject. In general the author's conclusions are in agreement with those of recent authors in the Anglo-Saxon world.]

TRYPANOSOMIASIS

FERRIRA, F. S. da C. As tripanosomíases nos territórios africanos portugueses. Africa Ocidental (Angola e Guiné) Africa Oriental (Moçambique) [The Trypanosomiasis in Portuguese African Territories, West Africa (Angola and Guinea), East Africa (Mozambique)] 32 pp. 12 folding maps (2 coloured). In Portuguese and English. 1943.

In Angola and Portuguese Guinea, sleeping sickness is more important than animal trypanosomiasis, while in Mozambique the reverse is the case. The difference is associated with the nature of the country, the density of population, and the species of tsetse flies which transmit the infections. In all three colonies information is incomplete and further investigations and control measures are being planned and organized.

Angola—Sleeping sickness (*Trypanosoma gambiense*) is almost limited to the area north of Lat. 12°S though there are a few endemic foci further south. In the Congo Province the chief centre of infection 3,500 cases were diagnosed in 1947. Domestic stock of all kinds totals nearly 2 millions. Infections with *T. brucei*, *T. congolense* and *T. uniformis* occur but most of the animals are kept in the tsetse free southern part of the colony. Tsetse flies infest about one-third of the country chiefly in the north. *Glossina palpalis* (with the varieties *wellmani* and *fusripes*) is the commonest species and *G. morsitans*, *G. pallicera*, *G. f. f. f.*, *G. schoutedeni*, *G. brevipalpis* and *G. longipalpis* also occur. Measures against trypanosomiasis include diagnostic surveys of the population and treatment with drugs, periodical inspection of animals with slaughter or treatment of those infected, a certain amount of clearing of vegetation, and destruction of game. The service forms part of the Public Health Service.

Portuguese Guinea—Conditions in the central and southern parts are not well known but in the west and east in the areas surveyed sleeping sickness (*T. gambiense*) is pretty generally distributed, the incidence being higher in the west than in the east. Trypanosomes were found much more frequently by gland puncture than by blood examination, the proportion in 427 patients examined by both methods being 7.5:1. Many cases were in the nervous stage—83 per cent. in the west 88 per cent. in the east. In the west, where there are large tidal estuaries and mangrove swamps with evergreen vegetation, the population is much exposed to *G. palpalis* while in the east where the climate is drier with open bush and forest vegetation and where *G. morsitans* is present contact of man with tsetse flies is less though *G. palpalis* also occurs near the rivers. Domestic stock of all kinds totals about 334,000. Infection with

T. congolense, *T. vivax*, *T. brucei* and *T. theileri* occur and it is noteworthy that *T. brucei* was found in monkeys (*Cercopithecus aethiops*) of the mangrove swamps [*T. brucei* is omitted in the English translation which includes monkeys among animals infected with *T. vivax*], a further report by the veterinary staff will shortly be published.

Four species of tsetse flies—*G. palpalis*, *G. submorsitans*, *G. longipalpis* and *G. fuscus*—are present, the first being much the commonest and the last the rarest. Polymorphic trypanosomes were found in 2.7 per cent of 2,632 tsetse flies examined. Other blood sucking flies identified were species of *Tabanus*—*bignellatus*, *brucei*, *distichus*, *gratus*, *nigrostriatus*, *roseus*, *viridis*, *taeniola*, *variabilis*, *Chrysops distichipennis* and *C. longicornis*, *Haematopota decora*, *H. lacessens*, and *H. maculans*.

A delegation of the Lisbon Institute of Tropical Medicine forms a permanent sleeping sickness service and has three sections: (1) for investigation, (2) for diagnosis and treatment of sleeping sickness, (3) for combating tsetse flies.

Mozambique—There are only about 200-300 cases of sleeping sickness (*T. rhodesiense*) a year and they occur in somewhat isolated foci. Domestic stock of all kinds amounted in 1945 to nearly 1 million of which about 600,000 were cattle. In the areas important for cattle breeding, infections with *T. congolense* alone are the most widespread, mixed infections with *T. congolense* and *T. vivax* come next, pure infections with *T. vivax* are infrequent, and *T. brucei* infections are very rare, a few infections with *T. simiae* have occurred. Tsetse flies infest about three-quarters of the colony; the four species present are *G. morsitans* (the most important), *G. pallidipes*, *G. brevipalpis* and *G. austeni*. Mechanical transmission by other blood sucking flies is also thought to be important. The area of Viputo [see Horn, in this *Bulletin* 1948 v 45, 1068] is ideal for cattle breeding and has therefore been specially studied; the relative frequency of occurrence of pathogenic trypanosomes was: *T. vivax* 66.84 per cent, *T. congolense* 15.76 per cent and mixed *T. vivax* and *T. congolense* 17.4 per cent [these figures seem to conflict with the statement given above]. *G. brevipalpis* and *G. austeni* are present as well as other blood sucking flies—*Tabanus*, *Haematopota*, *Stomoxys* and members of the family Hippoboscidae.

The trypanosomiasis service is controlled by a Council formed from the Health, Veterinary and Agricultural Services, the Department for Native Affairs, and the Mission for the Fight against Trypanosomiasis; the last named is the executive body and consists of medical, veterinary and entomological sections. Clearing of vegetation is being done in several areas, DDT and gammexane are used, some destruction of game has been carried out, and infected people and animals are treated; phenanthridinium proved to be the best drug for animal trypanosomiasis [Antrycide is a later discovery].

Game reserves—In Angola there are 7 game reserves in tsetse free areas, in Portuguese Guinea there is 1, and in Mozambique there are 5, but in the last colony freedom from tsetse flies is difficult to maintain.

NORTHERN RHODESIA. Game and Tsetse Control Department. Annual Report for the Year 1945 [VAUGHAN-JONES, T., Acting Director] 15 pp. 1946. Lusaka: Government Printer.

— Annual Report for the Year 1946 [VAUGHAN-JONES, T., Director] 19 pp. 1947.

— Annual Report for the Year 1947 [VAUGHAN-JONES, T., Director] 16 pp. 1948.

Reference has already been made [this *Bulletin*, 1948 v 45, 879] to an interesting administrative arrangement in Northern Rhodesia. As the main

tsetse problem relates to *G. morsitans*. It is closely connected with game. The Government views the whole subject of game (both conservation and destruction) as it affects the economic needs of the country and for convenience adds Fisheries. The three subjects are administered by one department.

The three annual reports give much detail of considerable interest. One notices that human sleeping sickness (*T. adense*) has a tendency to persist in certain spots: for instance an area east of Fort Jameson. Here *G. morsitans* has been attacked, successfully it seems, by discriminative clearing and the destruction of game. Much of the land has been resettled in a carefully planned way and the success of the whole measure is shown by the fact that in some places the people have cattle. Another of these centres of sleeping sickness is the Feira District in the south-east. The situation here continues to give some anxiety and the human population has been withdrawn from a part of it.

It is noted that extensive use is made of roadside clearings to reduce the number of tsetse carried by vehicles. It is of course only a partial measure for it would be almost impossible to make a clearing so wide that no tsetse would come out to the road, but it appears to be valuable.

The southern limit of rinderpest is at present roughly speaking the boundary between Tanganyika and Northern Rhodesia. In order to prevent the southward spread of the disease an area has been marked off as a cordon along which game destruction is practised. The spread of rinderpest and the threat to territories further south is of considerable international importance.

Lewis D. J. *Glossina tachinoides* in North-East Africa. *Bull. Entom. Res.* 1949 Mar. v. 39 Pt. 4 529-30 [10 refs.]

The tsetse fly *Glossina tachinoides* Westwood 1850 is an important vector of trypanosomes in parts of West Africa. Although it was reported from Arabia by CARTER (*Brit. Med. J.* 1909 Nov. 17 1393) as long ago as 1906 this finding as the present author observes has been questioned by other workers as a dubious record to be accepted with caution. In any case the gap in its distribution between West and East Africa is considerable. In 1939 GIBBONI (this *Bulletin* 1940 v. 37 401) reported *G. tachinoides* from the Gambella district of Western Ethiopia which borders on the Anglo-Egyptian Sudan.

The present writer now reports on a single female specimen of *G. tachinoides* found by Dr. Bloss of the Sudan Medical Service at Agulle (8° 4' N. 34° 04' E.) which borders on the Gambella district. Agulle is a remote police post on a stream flowing from the Ethiopian hills towards the swamps of the Nile valley: it is difficult to reach at most times of the year. The fly was found when biting the collector near a pool in the stream bed. This is the first record of this species in the Anglo-Egyptian Sudan although many collections have been made of *G. falcipes* subsp. *f. scipes* and *G. morsitans*.

The gap in distribution of *G. tachinoides* includes swamps of the Sudd region, unsuitable for tsetse flies but also a large area to the west through which flow many tsetse-infested tributaries of the Nile system. It is not known why this species is not present in these tributaries but the author notes that many insects in the Sudan show great discontinuity in distribution probably owing to past climatic changes.

LAPEYSSONNIE, L. Un cas exceptionnel de pan-chimio résistance chez une trypanosomée [Pan-Chemoresistance in a Case of Sleeping Sickness] *Bull Soc Path Exot*, 1948, v 41, Nos 9-10, pp 613-20

The author reports two cases of long-standing sleeping sickness infection which were remarkably resistant to repeated courses of treatment by a variety of arsenicals (atoxyl, tryparsamide, and orsanine), by suramin, and by tartar emetic. One of these infections lasted for 8 years, and its course and treatment are described in considerable detail. The other lasted for 12 years, and is merely mentioned. The patients were exceptional among 46,878 diagnosed in a sector of the Pagouda area of Togo.

The case which is described in detail is of a girl first diagnosed in July 1938 when she was 4 years old. Trypanosomes sometimes reappeared, after a temporary remission, even during an actual course of arsenical treatment. In about six years the patient had received, per 20 kgm body weight, a total of 40.15 gm of various arsenicals, 16.8 gm suramin and 4.6 gm tartar emetic. She was then given several courses of pentamidine injections, and by about April 1947 the infection finally appeared to be sterilized. [Eventual sterilization is attributed to the pentamidine treatment, but this seems unlikely, since the dosage reported was minute—0.003 mgm per kgm for the first two courses of injections, followed by 1.0 mgm per 25 kgm for two later courses.]

The patient was subjected to 27 lumbar punctures between 1938 and 1947, and the cerebrospinal fluid remained normal throughout this period. She always had generalized enlargement of lymph glands, and developed an enlarged heart and systolic murmur, an enlarged tender liver, and crepitant râles at the bases of both lungs. These signs are attributed by the author to myocardial damage consequent on the long-continued infection. Nevertheless, the patient's general condition remained remarkably good.

In an interesting but highly speculative and controversial discussion the author gives his view that the drug-resistance was inherent in the trypanosome and not produced by treatment. He believes that the trypanosome was of animal and not of human origin, on the slender evidence of its drug-resistance, and its predilection for the lymphatico-blood system rather than the central nervous system. He draws attention to drug-resistant sleeping sickness exhibiting the following features—

- (a) a strictly delimited geographical localization,
- (b) predominance of long forms (32 μ) and high incidence of blood infections,
- (c) an increasing incidence since 1941,
- (d) relative benignity, cases often remaining in perfect health for 3 years.

The author postulates the theory [hardly acceptable in its entirety] that relatively heavy blood infections, as in these cases, result in a high production of antibodies, which get into the cerebrospinal fluid and protect the central nervous system. When the strain becomes older, either in an individual or in a community the power of reproduction decreases, antibodies become less numerous, and sero-resistant "biological mutants" are consequently able to penetrate into the central nervous system. Thus, the older a strain is, in the sense of adaptation to man, the less will it tend to be found in the blood and the more neurotropic does it become. In the extreme development along these lines, cases occur in which the lymphatico-blood stage is insignificant and the nervous stages predominate almost from the start, as in the "*grands suspects d'Ebolowa*" [see this *Bulletin*, 1946, v 43, 1122].

In discussion of this paper, MURAZ questioned whether irregular time-intervals between injections might not have contributed towards production of the drug-resistance described.

ROMAÑA C. Xenodiagnóstico colectivo. Índices de infección por *S. cruzi* de niños en escuelas de Catamarca, Chaco Formosa, Corrientes y Entre Ríos. [Incidence of infection by *T. cruzi* among school-children of Catamarca, Chaco Formosa, Corrientes, and Entre Ríos, as found by Xenodiagnosis.] *An. Inst. Med. Regional Tucumán* Argentina, 1948, Dec. v 2 No. 2 185-96, 9 figs. English summary

In 1946 ROMAÑA and his colleagues reported finding 34 positive (by xenodiagnostic methods) among 148 school-children (23.3 per cent.) in Tucumán Santiago del Estero and Catamarca (this Bulletin 1947 v 41 404). Since that time other school-children have been tested 34 in Campo Largo (in Chaco) of whom 3 proved positive. At two schools in Catamarca 15 and 1 children respectively were tested and 2 of each were positive. Here the dwellings are of adobe (sun-dried bricks) with wood and earth roofs and Triatomidae are to be found in them. In Mercedes a district in the middle of the Province of Corrientes 4 were positive out of 63 tested and 3 out of 69 in Entre Ríos. The rate was higher 9 out of 40 in Formosa where *T. infans* was found in large numbers. A spot map indicates the places visited altogether 233 children were tested and 23 (9.8 per cent.) were positive. It was observed that in the places with higher percentage of infection the dwellings were of a poor standard and the general sanitary conditions bad. H. Harold Scott

CONEJOS M. Cultivo de *S. cruzi* en embrión de pollo [Cultivation of *T. cruzi* in Chicken Embryo.] *An. Inst. Med. Regional Tucumán*, Argentina, 1948 Dec. v 2, No. 2 175-83 5 figs. English summary

The author recalls that in 1939 ROCHA and ROMAÑA inoculated 10 chicken embryos with *T. cruzi* 5 with a culture 3 with dejections of *Rhodnius prolixus* rich in *T. cruzi* and 2 with the blood of an infected guinea pig. With the exception of one of the last in which a trypanosome was found at the end of a week, all were negative. [See this Bulletin 1940 v 37 415.]

Now the author inoculated chick embryos of 10 days incubation with a glucose-agar liver broth culture of *T. cruzi* and after 4 days found nests of multiplying trypanosomes in the organs. Better results were obtained if 5-6-day embryos were used, instead of 10-day. Trypanosomes appeared in the circulation from the 10th day after inoculation and remained till hatching. At birth none was found in thin or thick blood film but xenodiagnosis was positive in one instance on the first day of life. On the 7th day nests of developing trypanosomes were seen in all the organs heart liver spleen kidneys glands, muscles lungs and bone marrow. H. Harold Scott

SENECA H. HENDERSON E. & HARVEY Martha. Purification of Hemoflagellate Cultures with Antibiotics. *Amer. J. Trop. Med.* 1949 Jan., v 20 No. 1 41

Neither penicillin in 1,000 units and 5,000 units per 5 cc. supernatant overlay nor similar amounts of streptomycin nor 5,000 units each of penicillin and streptomycin together had any effect on the vitality and the intensity of the growth of *Leishmania donovani* and *Trypanosoma cruzi*.

For the purification of contaminated cultures of hemoflagellates 5,000 units of penicillin and 5,000 units of streptomycin added to such cultures in 5 cc. of saline ordinarily kills all contaminants in the second generation.

MANSO SOTO, A E & MARTÍNEZ, A La colección de triatómidos de la M E P R A [The M E P R A Collection of Triatomata] *Universidad Buenos Aires Misión de Estudios de Patología Regional Argentina Publicación No 74* 1948, 1-18, 5 figs

ROMAÑA, C & ABALOS, J W Acción del "Gammexane" sobre los triatómidos "Control" domiciliario [Control of Domestic Triatomata with Gammexane] *An Inst Med Regional Tucuman, Argentina* 1948, Dec, v 2, No 2, 95-106, 5 figs English summary

Preliminary laboratory experiments with Gammexane involved contact of nymphs and adults of various domestic species of *Triatoma* with variable proportions of gamma isomer mixed with inert dusts. One part of Gammexane in 2,000 gave 100 per cent mortality in twenty-four hours. A surface with 500 mgm/sq metre Gammexane caused the *Triatoma* to show toxic symptoms and finally to die. DDT was less effective—whereas 100 per cent mortality of adults could be obtained with DDT, the nymphs were more resistant, only approximately 50 per cent were killed and this percentage did not increase with increasing concentrations of DDT.

An account of the use of Gammexane as (1) a fumigant and (2) in water mixtures in rural areas in Argentina is given.

(1) The use of smoke generators was found to be ideal for the treatment of houses.

(2) In water suspensions the gammexane used contained 10 per cent gamma isomer and was made up at the rate of 25 and 50 gm per litre—a concentration of 500 mgm Gammexane per sq metre applied to roofs and walls of dwellings was found to be the most effective. The necessity for treatment of furniture and household goods for complete eradication is emphasized. This treatment gives protection against reinfestation for six months and is excellent for a large scale campaign.

PETRISHCHEVA, P A [Sandflies (*Phlebotomus*) in various Landscape Zones of USSR I Sandflies in Hot Deserts in Central Asia] *J General Biol* Moscow 1946, v 7, No 1, 65-84, 4 figs [15 refs] [In Russian] [Summary taken from *Rev Applied Entom* Ser B 1949, Feb, v 37, Pt 2, 19]

In view of the discovery by Latushev that cutaneous leishmaniasis occurs in natural foci and the probability that visceral leishmaniasis and sandfly fever also do so, the distribution of sandflies (*Phlebotomus*) in their natural habitats has become of epidemiological importance. Investigations were therefore made in the deserts in Turkmenistan, southern Tadzhikistan and Uzbekistan. Most of the work was done in sand desert, loess desert, which is covered with ephemeral vegetation, and stone desert, and little material was obtained from salt desert. The sandflies, which were collected chiefly on sheets of sticky

paper were very numerous and comprised practically all the species of *Phlebotomus* that occur in Central Asia, but each had its regions of prevalence. They were common in the burrows of gerbilles (*Rhombomys opimus*) and ground squirrels (*Spermophilopsis leptodactylus*) in the sand desert, the burrows of tortoises in the loess desert, and holes occupied by wolves, jackals and foxes in the stone desert. Detail are given of their seasonal occurrence and abundance in or near these places, and the species associated with each are enumerated.

The conditions that render the burrows or holes of animals in the desert suitable for the breeding of sandflies are discussed. The microclimate in them is characterised by a rather high humidity and moderate temperature, and they afford shelter from the extremes of summer heat and winter cold and the strong drying winds that prevail outside. Moreover they are frequently used as temporary shelters by various small mammals, reptiles or birds, on which the sandflies probably feed. Reptiles are abundant in the sand desert and notes are given on the species that occurred in the burrows of *Rhombomys* in association with *Phlebotomus* spp.

Sandflies were abundant in and near the burrows of *Rhombomys* and *Spermophilopsis* in the sand desert from the end of April till the middle of July and readily attacked man in the evening. Their frequency varied with the size of the rodent colonies. They occurred at fairly great distances from the burrows during the evening and night and it was often observed that they left them in numbers in the evening and returned in the early morning hours. Tortoises were numerous in the loess desert and were active for about three months from March when the vegetation appears until May when it dries up. They then remain dormant in their burrows for nine months after having blocked the entrances with a thick layer of soil. Sandflies were common from mid April until early May but none was observed after the end of May until the following spring. There was thus apparently only one generation a year with a long developmental period in the burrows. In the stone deserts in the mountains, sandflies occurred from April to the end of November in holes occupied by wolves and were most abundant for about two months in early summer. They were also numerous in the holes of jackals and foxes. They flew out during the evening and night and readily attacked man.

FEVERS OF THE TYPHUS GROUP

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE. SECTION ON MEDICAL SCIENCES. Rickettsial Diseases of Man.

This book is reviewed on p. 590.

FREEMAN G. VARELA, G. PLOTZ H. & ORTIZ MARIOTTE C. Typhus Fever in Mexico: a Study of Epidemiology by means of Complement-Fixation. *Amer. J. Trop. Med.* 1919 Jan. v. 29 No. 1 63 p. 2 figs.

This study was carried out in 1914-1915 and had the benefit of the collaboration of the late Colonel Harry Plotz. It is of special interest in connexion with the widely held belief that louse-borne typhus in Mexico often originates from murine rickettsiae which are capable of adapting themselves to transmission from man to man by lice.

Out of the 237 serum samples collected from all over Mexico in which positive reactions were obtained with complement fixation test at titres of 1/10 or over the great majority (184) gave higher titres with epidemic antigen. 48 had dominant murine antibodies and the remaining 5 which were negative

for epidemic and murine antigens, reacted with Rocky Mountain spotted fever antigens. The predominant type was, therefore, the epidemic, but in some areas murine infection was dominant, and in others it occurred side by side with epidemic infection.

In two isolated epidemics in which it was suspected that infection had originated from a murine strain the reactions showed that the earliest cases were epidemic in type. These two "negative instances" are not regarded as conclusive in themselves and the cautious conclusion of the authors is that "any suspected immunological relationship between the murine and classical types is not self-evident from these observations."

In some proved cases of typhus the titres had fallen below 1-10 two to four years after infection.

John W D Megaw

FREEMAN, G, CASTILLO SOLOGUREN, F & ESPINOSA, H Typhus Fever in Peru a Study of Epidemiology by means of Complement-Fixation *Amer. J. Trop Med* 1949, Jan, v 29, No 1, 71-8, 4 figs

This study was carried out on the same lines as the one described in the preceding abstract. Out of 374 serum specimens collected from all over Peru, and received in Washington in good condition, 192 gave positive complement-fixation reactions, and in every case this was of the epidemic type. The infected regions were exclusively the elevated *sierra* and *altiplano* areas of Central and Southern Peru, the small number of positive specimens received from the coastal cities were from persons who had come from crowded villages in the *sierra*.

There was evidence that the titre of the reaction tended to fall after about six months and that negative reactions after that period did not necessarily exclude the diagnosis of typhus.

John W D Megaw

WEYER, F Die Kleiderlaus als therapeutisches Testobjekt (Zugleich ein Beitrag zur Wirkung von Penicillin auf Rickettsien) [The Body Louse as a Subject in Chemotherapeutic Tests] *Ztschr f Hyg u Infektionskr* 1948, v 128, Nos 5/6, 499-505

The louse was found very tolerant of intrarectal injections of various chemicals such as sulphonamide solutions, penicillin, etc.

The insects were first inoculated by Weigl's method with typhus rickettsiae and then with chemicals whose therapeutic value was to be tested.

Para-aminobenzoic acid was found completely inactive but penicillin, given at intervals of three, twenty-four, and forty-eight hours, after inoculation, was remarkably effective, causing complete inhibition of growth in seven out of nine batches, each consisting of 30 lice. The action of the drugs was judged by examining stained smears of the guts of the lice. Apart from one batch of lice treated with penicillin which had accidentally become inert the result was that out of 148 lice examined after treatment only one was found to harbour visible rickettsiae, whereas among untreated control lice 77 per cent were positive.

The author admits that the louse serves practically as a test tube and that the results must be regarded as preliminary and tentative. He suggests, however, that the method may possibly be applicable to the testing of vaccines [presumably by introducing the vaccines into the rectum and later inoculating the insects with virulent cultures].

John W D Megaw

CARRERY L. & MOUTARDIER G. Note sur l'agglutination du *Proteus* O19 par des sérums humains et en particulier par des sérums de femme enceinte [Note on Agglutination of *Proteus* O19 by Human Sera, in particular by Sera from Pregnant Women.] *Ann Biol Clin.* 1948 Sept. Dec. v 6 Nos. 9 10 524-6

GRATCH [this Bulletin 1944 v 41 197] found that a large proportion of sera from pregnant women agglutinated *Proteus* O19 often to high titres. The present authors examined sera from various sources by a slide agglutination method, the results being classified as positive (agglutinating in less than two minutes) late or false positive (agglutinating in over two minutes) and negative. Of 57 sera from women who were pregnant or had recently been confined, 35 were positive and one was negative the remaining serum giving a late positive result. Of 493 sera from men or non-pregnant women 133 were positive 202 were negative and 148 gave a late positive result. The positive sera from pregnant women were tested by a tube method. The mean titre was 1/40 and no titre higher than 1/90 was recorded. High titres as reported by GRATCH were thus not found in the present series. The authors suggest that the only practical application of their observations would be in the diagnosis of pregnancy, since a negative test is not likely to be found in a pregnant woman.

ZALMAN M. DAVID P. & HORTOPANU Reactii biologice in "tifosul exantematic." [Biological Reactions in Epidemic Typhus.] *Rev Ch Medic Med* Bucharest 1948 July-Aug v 37 Nos. 7-8 352-66 3 figs. French summary

Because of the clinical analogy between uraemia and nervous forms of epidemic typhus, the authors studied certain biochemical reactions in the blood and urine of 180 in-patients in a hospital in Timisoara Rumania.

Blood urea was increased in all nervous and cerebral forms and its level has an important prognostic significance when it exceeds 1 gm. per thousand a fatal result may be expected.

Chlorides were found to be diminished in blood and urine alike in every case and this was particularly significant in the early stages.

Blood sugar was normal in the common forms but it was variable in the graver cases.

Uric acid was always increased usually from the end of the first week.

The Takai's Ara reaction was usually found positive especially in the severe forms. The authors state that when the intensity of this reaction is parallel with that of the Weil Felix the prognosis is good but when it is accompanied by a low titre of the Weil Felix reaction the prognosis is grave.

As a result of these observations the authors recommend that repeated examinations of blood urea should be made in every case of epidemic typhus, and that when it is increased, treatment appropriate to uraemia should be instituted. They also recommend that in severe cases the patient should be flooded [monitored] with normal saline by every possible route so as to re-establish the normal chloride level in the blood and urine. The cerebrospinal fluid was also studied biochemically in 10 cases only. From these few studies, the authors suggest that the result may serve to distinguish between the true meningo-encephalitic and the other nervous form of the disease. In the former case it shows meningeal or encephalitic features and in the latter a toxic picture.

ZAHARIA, N I & BERNFELD, M Viteza de sedimentare a hematului in cursul tifusului exantematic [The Erythrocyte Sedimentation Rate in Epidemic Typhus.] *Rev Stiintelor Med* Bucharest 1948, Sept-Oct, v 37, Nos 9/10, 463-74 French summary

The following is a translation of the authors' summary —

During the first week of the disease, the sedimentation rate is somewhat variable in most cases, the values vary between 0 and 20 mm after 1 hour. Towards the end of the period, the sedimentation rate increases to 30 or 40 mm after the first hour. During convalescence, it is maintained at this level. There is no correlation between the gravity of the illness and the height of the sedimentation rate. When there are suppurative complications, the rate is appreciably increased. The estimation of the sedimentation rate is of relative value in prognosis, but it may be useful for making a differential diagnosis in certain cases [See also this *Bulletin*, 1949, v 46, 45] H J O D Burke Gaffney

SCHOENBACH, E B Aureomycin Therapy of Recrudescant Epidemic Typhus (Brill's Disease) *J Amer Med Ass* 1949, Feb 12, v 139, No 7, 450-52, 1 chart

"A 42 year old Rumanian born man, ill with recrudescant epidemic typhus (Brill's disease), was treated on the sixth day of disease with aureomycin by oral and intramuscular routes. Prompt clinical improvement was observed. This is the first case of Brill's disease with a serologic pattern consistent with recrudescant epidemic typhus to be reported in Baltimore "

GIROUD, P & CIACCIO, G Valeur antigène et pathogène des précipitats de poulmon de lapin infecté de rickettsies épidémiques et murines par l'alcool méthylique [The Antigenic and Pathogenic Potency of Precipitates, obtained by treating with Methyl Alcohol, of Lung Suspensions of Rabbits infected with Typhus Rickettsiae] *C R Soc Biol* 1948, Oct, v 142, Nos 19/20, 1222-3

Suspensions of rabbit lungs infected with rickettsiae were treated with varying strengths of methyl alcohol and kept for two to seven hours at varying temperatures, the precipitates were separated by centrifugation and then tested by intradermal inoculation of rabbits. The resulting dermal reactions were regarded as showing the degree of virulence of the precipitates, and it was found that when the alcoholic strength was 30-40 per cent the reactions were feeble, although the production of agglutinins in the inoculated animals was almost as great as when untreated suspensions were injected.

This result suggested to the authors that alcohol treatment might be a suitable means of obtaining attenuated living vaccines

SERGEANT, Ed, PARROT, L & HORRENBERGER, R De la prévention des épidémies de typhus exanthématique par des vaccinations collectives en région d'endémicité pendant les périodes interépidémiques [Prevention of Typhus Epidemics by Mass Inoculation in Endemic Regions in the Inter-Epidemic Periods] *Bull Acad Nat Méd* 1949, v 133, Nos 3/4, 62-3

Epidemic typhus in Algeria is commonly cyclical, occurring in severe "waves" of 3 or 4 years' duration, followed by a subsidence for 8 to 12 years. The authors discuss the epidemiology of this cycle and the need, between the epidemics, to support the resistance of communities in foci liable to become re-attacked.

The non living vaccine of Durand and Giroud is very effective but its protection is short lived. In the face of an epidemic, re-inoculation is desirable every six months. The authors describe a plan for yearly mass inoculation in known epidemic foci of typhus during the post-epidemic period. The vaccine does not give severe reaction but there is the practical difficulty of giving three weekly doses of 1 cc. each to people as scattered as rural Algerians. For this purpose the vaccine has been replaced by one which contains in a single dose of 2 cc. the same number of organisms as there are in the 3 cc. of the three spaced doses of 1 cc. each. The stronger dose seems to be without ill-effect, and thousands of people in these affected areas have in fact already received it, no serious results have been reported. The authors add that, where possible, the course of three spaced weekly doses of 1 cc. each should be adhered to in the case of unusually susceptible persons such as non-immune Algerians, new arrivals from Europe and young children. *H. J. O. D. Burke-Gaffney*

BOCK, MARIANNO & KIKUTHI, W. Zur Frage der chemotherapeutischen Beeinflussung des Fleckfiebers (Chemotherapeutische Action on Typhus). *Alin Woch* 1948 Nov 15. 28 Nov. 43-44 691-4 2 figs.

2,2,2 trichlor 1,1-di-(4-nitrophenyl)-ethane provisionally known as Pb 832, is a new compound with an action on murine typhus. Its structural formula is —

It is insoluble in water but can be suspended in oil or in a commercial preparation Solvent M. Toxicity is low: an oily suspension of 20 mgm. is well tolerated by a mouse of 20 gm. body weight both by the subcutaneous and oral routes. Subcutaneously a dose of 40 mgm. per 20 gm. body weight kills, but a dose of 30 mgm. is not fatal. By mouth a dose of 70 mgm. per 20 gm. body weight kills but 40 mgm. are well tolerated. An oral dose of 2.5 mgm. of the oily suspension daily for five days gives good therapeutic result in mice infected with murine typhus. A daily dose of 2.5 or 5 mgm. for 8 days of the drug in solvent M is curative both subcutaneously and orally. If the rickettsiae are inoculated intranasally the therapeutic action is much less in evidence. The action of Pb 832 is apparently specific for rickettsiae: for the compound has no action on the viruses of influenza, lymphocytic choriomeningitis, louping-ill, and bronchopneumonia of mice or on spirochaetes, spirilla, the larva of rat leprosy, trypanosomes or malaria parasites. *G. M. F. Fuller*

CROSS, H. F. & SVYDER, F. M. Field Tests of Uniforms Impregnated with Mite Toxicants: I. Protection Studies (CROSS & SVYDER). *J. Econom. Entom.* 1948 Dec. v. 41 No. 6, 896-99. Part II. Stopping Time Studies (SVYDER & CROSS). *Ibid.* 940-41.

During the second World War benzyl benzoate was used for impregnating uniforms for protection against mites responsible for scrub typhus infection. In the course of a search for chemical more resistant to washing than benzyl benzoate 6,000 material were subjected to screening test and finally eighteen of them were compared with benzyl benzoate. Of these five were selected which did not stain, cause skin irritation or have an undesirable odour. These were — benzyl benzoic acid, phenyl ester benzoic acid, α -thienyl ester diphenyl carbonat and salicylic acid. α -thienyl ester

Tests were carried out to determine—

(i) The protection given to wearers of uniforms impregnated with test materials at 2 mgm /sq ft of cloth. The evaluation of protection was based on the number of mites attached to subjects wearing these uniforms in heavily infested areas over 1–2 hours. The mites were counted 3–5 hours after exposure and tests were made after the second, third, sixth and other washings of the garments.

Phenyl benzoate, diphenyl carbonate and 2 thenyl salicylate gave 100 per cent protection through seven washings, 2 thenyl benzoate through six washings. Benzyl benzoate gave 99 per cent protection after the third washing, and none after the fourth. With benzil, protection decreased from 99 to 83 per cent after eleven washings.

(ii) The time required to immobilize mites confined to impregnated cloth.

There was found to be a correlation between the time taken for the immobilization of mites and the protection achieved. Substances giving a protection of over 90 per cent caused immobilization of mites in fifteen minutes or less. The intervals between the time the mites first become affected and are finally immobilized increases with the number of washings, this applied to all materials.

PARKER, R. R., BELL, E. J. & STOENNER, H. G. Q Fever—a Brief Survey of the Problem. *J Amer Vet Med Ass* 1949, Feb & Mar, v 114, Nos 863 & 864, 55–60, 124–30 [61 refs]

NAUCK, E. G. & WEYER, F. Der Erreger der "epidemischen Bronchopneumonie des Menschen" (Herzberg) und seine Beziehung zur *Rickettsia burneti* (Q fever). [The Organism of "Human Epidemic Bronchopneumonia" (Herzberg) and its Relationship to *Rickettsia burneti* (Q Fever)] *Ztschr f Hyg u Infektionskr* 1948, v 128, Nos 5/6, 529–50, 8 figs [30 refs]

The ostensible purpose of this paper is to show that a strain of infection described by HERZBERG in 1946 as the filterable virus of human bronchopneumonia is really the rickettsia of Q fever. The strain, in fact, appears to be the one isolated by Caminopetros in Greece in 1943 and later identified in the U S A as *Rickettsia burneti* by the Commission on Acute Respiratory Diseases [see this *Bulletin*, 1947, v 44, 68].

The authors were severely handicapped in their study of the strain by the fact that no standard strain of *R. burneti* was available for the crucial tests of cross immunity and complement fixation reactions, but the detailed description of the morphology of the rickettsia and of its behaviour in experimental mice, guinea-pigs and various arthropods leaves little room for doubts regarding its identity with *R. burneti*.

A specially interesting feature of the investigation was the intrarectal inoculation of lice and fleas by virulent suspensions, in body-lice rickettsiae were still present in the faeces 24 days after inoculation, but only in small numbers. In the mouse-flea, *Leptopsylla segnis*, growth occurred much more actively. Intracoelomic inoculation of ticks, especially *Ornithodoros moubata*, was very successful, infection persisted up to 282 days and the coxal fluid of the ticks was infective to mice up to 67 days after inoculation. These findings suggested that the tick is likely to be an effective natural vector. The organisms multiplied readily in the fat bodies of the grain weevil, *Tenebrio molitor*. The ease with which development occurred in different arthropods corresponded to similar findings in connexion with *R. prowazeki*, *R. mooseri*, and *R. orientalis*,

and did not suggest that natural transmission was likely to occur by all the arthropods concerned, though it did suggest a close relationship with the rickettsiae of the fevers of the typhus group.

The morphological features of the rickettsiae are fully described and are illustrated by excellent photomicrographs. In average size they appeared to be rather smaller than the rickettsiae of the fevers of the typhus group but otherwise they were similar in all essential respects. The peritoneal cells of inoculated mice were not found to be invaded—the chief concentration of the organisms was in the spleen. No special tendency to invasion of the lung cells was observed even after intranasal inoculation.

The proposal of PHILIP to create a new subgenus, *Coriella* is regarded as premature and agreement is expressed with the present reviewer's comment on Philip's proposal [see this *Bulletin* 1943 v 40 828]. A protest is made against the use of such names as "atypical," "primary atypical, benign, and epidemic" pneumonia—these names are regarded as meaningless and although pneumonic lesions are common they are far from being essential features of the disease.

Full justice cannot be done to the paper in an abstract. If, as seems likely the rickettsia turns out to be *R. boravia* the study will take its place as an important contribution to knowledge of that organism.

YELLOW FEVER

GARNEHAM P. C. C. Aerodendrophilic Mosquitoes of the Langata Forest, Kenya. *Bull. Entom. Res.* 1949 Mar. v 39 Pt 4 489-90

After a human case of yellow fever had been traced to Langata Forest, near Nairobi Kenya in 1943 it was shown that a mild focus of yellow fever existed there probably the highest in Africa (6000 feet). Observations on forest mosquitoes were begun and later extended to include those in the tree tops.

The numbers are given of the females of eight species of *Aedes* caught on an African child on a platform built in a tree 30 feet from the ground. Catches were made from 7 to 10 a.m. and from 5 to 8 p.m. six times a week from May 1946 to March 1947. *Aedes deorsi* were the most numerous with 28 caught in the mornings and 154 in the evenings. One *Aedes aegypti* was caught. Other platform catches yielded similar results. Simultaneous catches at ground level revealed a wide range of mosquitoes but only nine specimens of *Aedes deorsi* were captured.

Attention is drawn to the following points—the presence of *Aedes aegypti*, the relative abundance of *Aedes deorsi* in the forest but not at ground level, the absence of *Aedes africanus* a known vector and of *Aedes adersi* a suspected vector. The investigation was admittedly on a small scale and in the circumstances it is not possible to say more than that *Aedes deorsi* may be the jungle vector of yellow fever in Langata.

H. S. LARSEN

DICK, G. W. A. & SMITHSON, K. C. Immunity to Yellow Fever Six Years after Vaccination. *Amer. J. Trop. Med.* 1949 Jan. v 29 No 1 57-61

Recently ANDERSON and GAST-CALVIS [see this *Bulletin* 1947 v 44 815] reported that neutralizing antibodies were present in the sera of 83 per cent. of a group of 823 people in Colombia who had been injected with a vaccine made from the 17D strain of yellow fever virus at least five years previously.

The present authors have made a similar observation in Uganda in Central Africa. They found that 91.8, 86.5, 82.8 and 87.4 per cent of four groups injected with the 17D strain of yellow fever virus vaccine still had demonstrable neutralizing antibodies in their serum six years later. Tests of sera from groups of children aged six years or less in each region gave no indication that the yellow fever virus had been present in these areas since the vaccine had been injected. [It is probable that the remaining 17.2-9.2 per cent also have some residual immunity but at a level below the sensitivity of the mouse neutralization test.] These results confirm the validity of the certificate of yellow fever immunity for four years, provided that the required dose of active virus has been injected in the vaccine. The results also agree with those of Anderson and Gast-Galvis in showing no significant difference in the immune response of adults and children. [See also this *Bulletin*, 1943, v 40, 451, 1946, v 43, 34]

RABIES

PICKAR, D N & KRAMER, H M. Encephalitis complicating Vaccination for Rabies. Report of a Case treated with Antihistamine Agents. *Southern Med J* 1949, Feb, v 42, No 2, 127-30

In the article under review the authors describe the hitherto untried treatment with antihistamine agents of a case of that very infrequent reaction to antirabies vaccination, encephalomyelitis without paralysis.

The patient, a 26-year-old white man, without history of personal or familial allergic disorders, was admitted to hospital 20 days after having been bitten by a rabid cat. Daily injections of Semple's phenol-killed vaccine were begun some days after the date of biting and were continued over a 10-day period. After the seventh injection the patient noticed swellings at the sites of inoculation, after the tenth injection he became feverish, and suffered progressively increasing frontal headache, somnolence, nausea, vomiting, muscular soreness and diplopia. Thereafter vaccine treatment was discontinued and the patient remained at home in bed for some days, until his condition became so alarming as to necessitate his removal to hospital. On admission he was mentally confused and disorientated, with a temperature of 102°F, there was marked nuchal rigidity, but the Kernig and Brudzinski signs were negative. Neurological examination was otherwise normal. The report of the electro-encephalogram read: "The impression is of a moderately and diffusely slow electro-encephalogram compatible with diffuse encephalopathy." The cell count showed in the cerebrospinal fluid 240 cells per cmm, 89 per cent lymphocytes, 11 per cent polymorphonuclears.

Hospital treatment consisted first in the administration of 500 cc of pooled plasma to ward off the impending circulatory collapse. Antihistamine agents were then exhibited, because of the possibility that the condition might be allergic. 100 mgm of benadryl were given intravenously in 1000 cc of 5 per cent glucose in saline, and 100 mgm were administered by the mouth 4 hours later. Prompt improvement in all symptoms followed, with gradual fall in the temperature to normal within 16 hours. Benadryl was continued in doses of 100 mgm orally 3 times a day until the patient's increasing somnolence compelled its discontinuance after the ninth dose. During the succeeding 24 hours, no antihistamine drug was exhibited and there resulted a temperature rise to 99.6°F, accompanied by return of severe frontal headache and diplopia. Reinstitution of antihistamine treatment with pyribenzamine in doses of 100 mgm 3 times daily caused almost immediate cessation of headache and

return of the temperature to normal. Such pyribenzamine treatment, continued for the next 7 days succeeded in rendering the patient wholly asymptomatic, although the cerebrospinal fluid contained 115 cells per cmm. 94 per cent. of which were lymphocytes. At this time there was marked improvement in the appearance of the electro-encephalogram and 18 days after admission the patient was discharged from hospital afebrile asymptomatic and completely able to walk.

In connexion with this case it is of interest and importance to note that, although without personal or familial history of allergic disorders the patient after intradermal injection of 0.1 cc. of a 1 in 100 dilution of the same material used for his antirabies vaccination developed on the forearm a wheal 1.5 cm. in diameter surrounded by a flare of 6 cm. and that on repetition of the test after 48 hours of pyribenzamine administration in the same dosage as had been used therapeutically, no skin reaction resulted.

Evidence is thereby adduced in favour of the view first advanced by McLENDON at the International Rabies Conference held in Paris in 1927 that anaphylaxis may play a rôle in the causation of the neuro-paralytic accidents of antirabies treatment—a view strongly supported by HORACK (this Bulletin 1939 36 730) and by THOMAS (*ibid* 1943 v. 42, 168).

The authors recommend that inasmuch as recovery followed the use of antihistamine agents in the present case further clinical trial of these drugs should be made in the treatment of the neuro-paralytic accidents of antirabies vaccination.

G. Stuart

VERGE M. J. Meurt-on encore de rage? (Does one still die of Rabies?) *Rev Path Compar* 1948 Dec., No 602, 583-5

The author introduces the subject of his enquiry by stating that deaths from human rabies totalled 151 in the hospitals of Shanghai during the period 1903-48 and 3,000 in the U.S.A. between the years 1903 and 1947. Moreover certain recently published reports challenge the value of anti-rabies treatment and imply that vaccination in man may not be as effective as originally believed. In his defence of Pasteurian treatment however the author refers to the statistical evidence of BATES and LEVINE *vi* that mortality among persons bitten by rabid dogs is from 9.3 to 70 per cent. in the untreated as compared with from 1 to 2 per mille in the treated, and stresses the need, in evaluating the result of anti-rabies treatment, for differentiation between "apparent" and "real" failures of vaccine therapy. Germane to the latter observation is the statistical results quoted from REMPEL and BAILY in respect of the several Anti-Rabies Services in French North Africa. Of 77,453 bitten persons treated, 262 died of rabies—147 being regarded as "apparent failures" 115 as "real failures of treatment." Real failures occurred most frequently among adults and, paradoxically enough, were consequent less on serious wounding than on slight exposures inadequately treated. Apparent failures obtained mostly among children or among persons bitten by wild animal such as wolves and jackals. To these failures the "altered virulence" of certain street viruses also contributed. The conclusion is reached that anti-rabies vaccination remains the sole effective means of combating the invasion of the human body by rabies virus. (The author defines failures of anti-rabies treatment as follows: "apparent" onset of rabies during treatment "real" onset during the weeks or months after treatment. In this connexion it is of interest to recall one of OTTEY's criteria for the drawing up of all rabies statistics on uniform basic principles. Individual treated, as well as deaths, should be classified according to age in view of the fact that experience has generally shown that the mortality is higher among children than it is among adults. Moreover the

method frequently employed, which consists in the suppression of any mention of the total mortality and indicates only the number of failures of treatment or cases in which symptoms developed 15 or more days after the end of treatment, may give a very erroneous impression of the results obtained, because the longer the duration of treatment the greater will be the number of cases of hydrophobia excluded from the "failures" It is therefore logical to use the date of the beginning and not that of the end of treatment from which to reckon the period on the lapse of which the appearance of symptoms implies a failure of treatment, the duration of treatment varying in different institutes This period might, for example, be fixed at 30 days, in accordance with the old custom of applying Pasteur treatment for 16 days, to which 14 days are added to make allowance for the intracerebral incubation period]

PLAGUE

- i KARAMCHANDANI, P V & RAO, K S Streptomycin in Human Plague compared with other Treatments *Lancet* 1949, Jan 15, 96-7, 2 figs
- 11 HILL, A B , BHAGWAT, S Y Streptomycin in Human Plague [Correspondence] *Ibid* Jan 29, 203

1 A group of 15 plague patients, specially selected as being apparently moribund, were treated by streptomycin Only three of them died, and these had been admitted after the 3rd day of the fever in a condition "indicating impending dissolution"

In another group of 32 patients, treatment was by sulphadiazine, combined in some cases with anti-plague serum, there were seven deaths so that there would have been no significant difference between the results of the two methods of treatment but for the fact that three of the patients who had become "apparently moribund" while under treatment by sulphadiazine, were saved by streptomycin, which the authors regard as superior to any other treatment

The dosage adopted was 0.5 gm every six hours, up to a minimum total of 1.0 to 2.0 gm and a maximum of 8.0 gm

11 In a letter to the *Lancet*, Professor Bradford Hill criticizes the authors' presentation of the case for streptomycin and describes it as consisting of pseudo-statistical "evidence" which is calculated to damage rather than further the reputation of the drug In the same letter an attack is made on the validity of the statistics presented by the authors regarding fatality rates among inoculated and uninoculated patients The authors state that among 120 inoculated patients the mortality rate was 27.5 per cent and among 80 uninoculated, 32.5 per cent The authors further state that the mortality rate was "composed of 18 per cent among those who had been inoculated 1-7 days, 4.5 per cent among those inoculated 7-14 days, and 9 per cent among those inoculated 14 days to 4 months before the onset of plague" The latter set of figures does not, as might be supposed, deal with the mortality rates for each of the three sub-groups but appears to have been obtained by dividing the deaths in each sub-group by the total 120 cases, irrespective of the date of inoculation, so that "the resulting figures have no meaning whatever"

In the same number of the *Lancet* Dr S Y Bhagwat also makes a trenchant criticism of the figures dealing with the mortality rates among inoculated and uninoculated patients He points out that if, as stated, immunity develops a week or so after inoculation the patients dying in the first week may rightly be

regarded as uninoculated and the figures will become 11.2 per cent. mortality among 98 inoculated against 46.3 per cent. among 103 uninoculated.

This is only one out of five points of criticism offered by Dr. Bhargava.

John W. D. Moore

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

WESTPHAL, A. Zur Epidemiologie und Pathogenese der Amöbenruhr in Nordafrika 1911/4... [The Epidemiology and Pathogenesis of Amoebic Dysentery in North Africa 1911-43.] *Ztschr. f. Hyg. u. Infektionskr.* 1943, July 16 v. 128 Nos. 1/2 73-86 4 figs.

These important observations were made in North Africa in soldiers of the Africa Corps in 1911-1914. The object was to determine the association between *Entamoeba histolytica* infection and the varied and numerous other intestinal affections encountered in North Africa. An experience in common with other campaigns in this area is that affections of the gastro-intestinal tract vastly outnumbered all other disabilities.

The study is richly illustrated with graphs, diagrams and statistical data which are difficult to summarize and sometimes are more difficult to interpret.

Amongst 1,069 men who were investigated during an average period of 10.4 months in N. Africa up to the autumn of 1914 81 per cent. had experienced one or more intestinal upsets which persisted for longer than three days and comprised every gradation from simple diarrhoea to severe dysentery. There was no apparent correlation between the *E. histolytica* infection and the "intestinal upset index". Even in a particular diagnosed intestinal bacillary infection the individual *E. histolytica* cyst-passers did not suffer more than those who were free from the protozoan. This observation indicated that *E. histolytica* could not be held responsible for the primary disturbance and this was confirmed by experiments made with stool filtrates obtained from *E. histolytica*-negative patients. On these premises it is suspected that in many intestinal disturbances there is a primary bacillary infection rather than a purely functional upset. In no less than 4,057 patients with clinical dysentery on the basis of the clinical picture and the microscopic faecal examination 96.3 per cent. could be diagnosed as primary bacillary and only 3.7 per cent. as amoebic dysentery. But in fact out of the large number (96.3 per cent.) of bacillary infections 7.6 per cent. were found to have a superinfection with lumen-inhabiting forms of *E. histolytica* and 1.4 per cent. could be considered to be suffering from a mixed infection of both bacillary and amoebic dysentery. The total infection-index for *E. histolytica* in these 4,057 dysenteries was no higher than the figures obtained from 981 investigated normal persons. The experience would entirely negate the supposition that this amoeba was responsible for the numerous bowel infections encountered, but rather so the author assures us his figures would support the conclusions deduced from his former self-inflicted experiments in 1937 and 1938 (this Bulletin 1939, v. 25 598 1939 v. 36 288).

From the protocols of several specially meant by investigated cases support has been obtained that a lumen infection with *E. histolytica* arises upon bacillary spoiling of the mucosa. Calculations based upon statistical analysis prove that in about one third of all *E. histolytica* cyst-passers who subsequently contract some bacillary infection of the gastro-intestinal tract the lumen infection develops into the classical *E. histolytica* tissue-invading phase.

P. Mansueto-Bale

VAN STEENIS, P B Enkele opmerkingen over amoebendysenterie en amoebiasis [Observations on Amoebic Dysentery and Amoebiasis] *Nederl Tijdschr v Geneesk* 1949, Jan 1, v 93 (1), No 1, 11-18 English summary (5 lines)

The author reviews our present knowledge of the pathogenesis, clinical course and diagnosis of amoebiasis. The discussion is on familiar lines, except for the interpretation of the life history of *Entamoeba histolytica*, in which the author follows KUENEN and SWELLENGREBEL [see this *Bulletin*, 1914, v 3, 76]. According to this view, in symptomless carriers and in chronic cases of amoebiasis the amoeba lives in the lumen of the gut as a commensal (the so-called *minuta* form) and is responsible for the maintenance of the infection in the same host and for its propagation to others by formation of cysts. Under certain conditions, the nature of which has not yet been clearly established, the amoebae may invade the intestinal wall, producing characteristic lesions and clinical symptoms. The tissue-invading amoebae feed on red blood corpuscles and are larger than the lumen-forms, which show some resemblance to *E coli*. Indirect evidence of the existence of a lumen-dwelling phase of *E histolytica* is provided by the enormous numbers of cysts passed by carriers and chronic sufferers, which are out of all proportion to the small number of tissue-inhabiting amoebae that may be present in lesions, which, according to FAUST [this *Bulletin*, 1941, v 38, 590], are found in all such cases. The present paper is an example of a growing tendency to reconsider our views on the host-parasite relations in amoebiasis, in the light of recent observations on the behaviour of *E histolytica* in cultures and in infections (natural and experimental) of lower mammals [*ibid*, 1948, v 45, 76].

RITCHIE, L S & DAVIS, C Parasitological Findings and Epidemiological Aspects of Epidemic Amebiasis occurring in Occupants of the Mantetsu Apartment Building, Tokyo, Japan *Amer J Trop Med* 1948, Nov, v 28, No 6, 803-16, 1 fig [11 refs]

This paper reports epidemiological observations and parasitic findings in the Mantetsu apartment building in Tokyo, in January 1947.

The Tokyo water supply had been declared potable. At the time the epidemic was exposed, 73 families of American officials were housed in this building, and a total of 161 persons has been taken into consideration. The arrival dates ranged from 15th November 1946 to 25th January 1947. The rates of protozoan infections in this group prior to their residency in Mantetsu can be little more than speculation and there was no reason to believe that they entered the building with the strikingly high rates they were later proved to have. Although some of the men had spent considerable time overseas, this was not true for the women.

Of the employees, 248 Japanese employed at the building were subjected to multiple stool examinations and were divided into two categories—food handlers and non-food handlers, and on the basis of the control of 15,000 stool examinations on other Japanese Nationals the pre-epidemic protozoan infection rates for the Mantetsu group were estimated to be *E histolytica* 7-10 per cent, *E coli* 15-18 per cent, *Endolimax nana* 10-15 per cent, *Giardia intestinalis* 5-8 per cent and *Chilomastix mesnili*, 1-2 per cent.

Numerous cases of diarrhoea were noted early in January 1947, but the symptoms were so moderate as hardly to attract attention. Out of sixteen stools, half were positive for *E histolytica* (stage not stated). These findings were considered sufficient to warrant the investigation of the water system and dining facilities. The procedure adopted was divided into several phases

Initial examination—The general policy was to examine two or more stools before treatment.

Second phase—If *E. histolytica* had not been diagnosed after 3-5 examinations, the person concerned was examined again twice at weekly intervals and then twice at bi-weekly intervals before being declared free of *E. histolytica*.

Post-treatment examinations were made immediately after treatment and subsequently at intervals of 2, 4, 8 and 12 weeks.

Terminal examinations—Two stools of each occupant were examined at the end of six months. Most diagnoses were made on cysts. When only trophozoites were present the diagnosis was tentative unless typical motility was observed. Saline and iodine direct smears and a microscopic preparation from an ether-sedimentation concentration technique were searched in each specimen submitted.

Adults at the Mantetsu numbered 151 and of these *E. histolytica* was found in 62.9 per cent, while the probable incidence prior to residence in the Mantetsu was estimated to have been 5 to 10 per cent.

One or more protozoa were harboured by 5.4 per cent of the Japanese and the incidence of *E. histolytica* was 22.2 per cent, while *G. subcolonialis* was the most commonly encountered protozoan in both Japanese and Americans.

As in the case of the Chicago hotel epidemic of 1933 [see *Bulletin of Hygiene* 1934 v 9 178-315], no significant difference existed in the susceptibility of the sexes for any of the intestinal protozoa. Among the Japanese the percentage of incidence was approximately the same in those who handled food and in those who did not.

Investigation of the sewage system in the sub-basement revealed a considerable leakage and probable contamination of the water supply. The massive nature of the protozoan infections rendered it unlikely that any agency other than water could have infected so many persons in such a short period of time.

[The large percentage of *E. histolytica* cysts in the faeces combined with apparent absence of acute cases with blood and mucus in the stools would seem to militate against a proven epidemic of amoebiasis.] P. Manson-Bale

DAVIS C. & RITCHIE, L. S. Clinical Manifestations and Treatment of Epidemic Amebiasis occurring in Occupants of the Mantetsu Apartment Building, Tokyo Japan. *Am J Trop Med* 1948, Nov v 28, No 6, 817-23

The clinical manifestations and treatment of one hundred cases of amoebiasis occurring among American occupants of the Mantetsu apartment building [above] are described.

The relative mildness of the clinical manifestation is ascribed to the brief period of exposure to infection with *E. histolytica*. Fully 45 per cent. gave no history of gastro-intestinal complaints since arriving in Japan. Diarrhoea was the most commonly reported finding and approximately 40 per cent. of patients noted one or more episodes of 2-4 days duration of only "3 loose stools per day". Approximately 28 per cent. averaged 4-8 stools per 1 hour and only 7 per cent. averaged 8-15 stools during the same period. A few rice-water stools were submitted. No microscopic or macroscopic blood was recognized in any of the stools. Practically all patients noted acute bloating, epigastric discomfort and varying degrees of lower abdominal discomfort after meals and approximately 10 per cent. reported anorexia and vomiting. There were no fatalities.

Seventy-4 of the patients were treated with carbarosone 0.3 gm. three times daily for 7 days followed by diiodoquin 0.63 gm. three times daily for 7 days. The remainder were given emetine hydrochloride 0.03 gm. intramuscularly.

twice daily for 7 days concurrently with carbarsone and diodoquin as above, they were those with more severe diarrhoea

Of the total number treated, three continued to pass cysts of *E histolytica* after one course of treatment, two of these had negative stools after a second course, while one child required four courses before the stools were found to be negative. Seventeen patients continued to have occasional episodes of mild diarrhoea or abdominal cramps in spite of repeated post-treatment negative stools

[The absence of blood and mucus from the faeces even in the more acute cases strengthens the view already expressed above] P Manson-Bahr

SENECA, H, HENDERSON, E & HARVEY, Martha The Synergistic Action of Penicillin and Streptomycin on *Endameba histolytica* Cultures Amer J Trop Med 1949, Jan, v 29, No 1, 37-9

"Neither penicillin nor streptomycin is amebicidal in concentrations of 100 to 1,000 units per cc. A combination of the two, however, in equal unitage, kills amebae in the first generation at a total concentration of 2,000 units per cc, and in the second generation at 1,000 units per cc. The latter concentration is found not to be bactericidal, hence the action is probably a direct one rather than an elimination of necessary bacterial products. Therapeutic application of the findings is suggested"

SENECA, H, HENDERSON, E & HARVEY, Martha Effect of Hyaluronidase and of Hyaluronic Acid on Cultures of Trypanosomes, Leishmania, and Amoebae Science 1948, Dec 24, 714-15

Hyaluronic acid is a complex polysaccharide which with its enzyme, hyaluronidase, is found in bacteria and animal species. The effect of these substances was tested on cultures of *Leishmania donovani*, *Trypanosoma cruzi*, and *Entamoeba histolytica*. The flagellates were unaffected both by direct treatment and after numerous subcultures in media containing these substances. In the presence of the enzyme, *E histolytica* became hyperactive with enhancement of growth, the acid, however, had a contrary effect, a dosage of 5 mgm per 5 cc sterilizing cultures after three generations.

It is suggested that hyaluronic acid might be usefully employed in the treatment of cases of amoebic dysentery (a) for its direct action on the organism, and (b) to inhibit the stimulatory effect of hyaluronidase. P C C Garnham

YAWS

HARDING, R D A Yaws Campaign in Sierra Leone Trans Roy Soc Trop Med & Hyg 1949, Jan, v 42, No 4, 347-66, 1 map [12 refs]

This campaign was carried out among a primitive peasant population of 276,000 in eastern Sierra Leone. Practically the whole population was examined and all active yaws cases were treated. The vegetation of the area is discussed.

It is about 400 feet above sea level and swamps are numerous. The rainfall is 80-95 inches and is heaviest in June to October when humidity is high.

The prevalence of yaws is undoubtedly correlated with social status and with hygiene. Secondary yaws lesions were most frequent during the wet season and least in the dry season. This must be taken into account in assessing the significance of changes in the incidence found at surveys after treatment at different seasons. Monthly examinations for one year of a population of 1400 in a place where insufficient treatment was given to affect the general picture showed that infectious lesions might be four times and non-infectious lesions over twice as frequent in the wet as in the dry season. About two-thirds of the whole population aged 10 years or over had been infected. At any one time up to 13 per cent. of infectious yaws lesions were found in some communities examined in the wet season. Non-infectious yaws included dry secondary lesions palmar and plantar keratosis, bone and all tertiary lesions. The author comments that late secondary non-infectious plantar lesions appeared to be much more frequent than in most parts of the world and in some areas comprised 80-90 per cent. of all yaws lesions. These lesions are aggravated by trauma and peasant occupations. (Plantar and palmar lesions urgently need thorough study. Their economic significance is rarely appreciated. The high incidence of these lesions in people aged 20-30 years compared with that of the remainder of the population, suggests that many may be tertiary lesions.)

A valuable table of the incidence of various yaws lesions in different age groups in a community of 4,500 shows that primary and secondary framboesiomata occurred chiefly in those under 10 years of age granulomatous plantar yaws were present equally frequently in the age groups 5-9 and 10-19 while non-infectious lesions were more frequent in those aged 20-30. This suggests a natural evolution of yaws. After 40 years of age yaws lesions gradually disappeared. This incidence is important in control in that attention should be concentrated on the younger sections of a community.

There was no evidence that any insects assist in transmission. Probably the most important factors in the spread of yaws are the crowding of naked children in hot humid, dirty mud huts and the absence of personal cleanliness. In Sierra Leone yaws is a house disease spread by direct contact.

The author discusses the organization of the campaign and stresses the long quiescent periods in the secondary stage which may end the infectious relapses. The essentials in order of time are (1) mass diagnosis and treatment (2) provision of permanent treatment centres placed so that no patient need travel more than 10-12 miles and (3) the establishment of itinerant yaws attendants who seek patients and send them to the nearest treatment centres. Treatment was given at intervals of 5 days to fit in with a campaign against trypanosomiasis.

The drugs at first used were acetylarsan (diethylamine acetarsol D.A.) and bismuth sodium potassium tartrate both given by intramuscular injection. At an early stage acetylarsan 5 cc (1.13 grammes D.A.) was found too toxic and the dose was finally reduced to 2.5 cc. (0.59 grammes D.A.) for 4 injections. The B.S.P.T., 5 grains (0.33 grammes) was found relatively ineffective and was finally replaced by bismuth salicylate 0.5 grammes in oil. The doses quoted are for body weight of 125 lb. (57 kilo) or more. Four to six injections of acetylarsan and B.S.P.T. (or acetylarsan and bismuth salicylate) were given concurrently. It was later learned that the B.S.P.T. (Dr Alexander's formula) contained only 4.34 per cent. bismuth metal while the bismuth salicylate B.P., contained about 58 per cent.

The clinical and serological results which have already been published by ARTED *et al* [this Bulletin 1948 v. 43 1066] showed that of infectious lesions

one year after treatment 64 per cent were free of lesions, 32 per cent had inactive plantar lesions and 4 per cent had active yaws. For non-infectious lesions, the corresponding figures were 34.2, 50.9 and 14.7 per cent. Of 250 cases 6 months to 2½ years after treatment with acetylarsan and B S P T, 29.2 per cent gave negative Kahn reactions and 32.8 per cent gave + weak or ± reactions.

After mass diagnosis and treatment alone there was some reduction of infectious yaws. When this was followed by permanent treatment facilities, the yaws incidence fell from 4-6 per cent to under 1 per cent in several years. When home visiting was also added, no infectious yaws was found in a sample of 1,500 of 7,000 people about 15 months after initial mass treatment, however, 8 months after all treatment facilities had been withdrawn the incidence had risen to half its original level. Non-infectious lesions decreased more slowly than infectious lesions.

The author discusses the theoretical aims of a yaws campaign as (1) total eradication of yaws, (2) elimination of infectious yaws, (3) reduction to a level that produces no serious suffering or inefficiency, (4) alleviation of symptoms by treating those who voluntarily seek attention. Since the correction of unhygienic conditions is at present impracticable, chemotherapy must remain the chief weapon in West Africa. Movements of individuals make complete eradication impossible. The author's opinion is that complete eradication is not without the danger of being followed by a big increase in syphilis. The marked tendency of relapse in the secondary stage makes elimination of infectious lesions more complicated than might appear. The reduction of yaws to a low endemic level became the purpose of the campaign reported, and this was achieved. Although treatment of patients presenting themselves does reduce the incidence of yaws, it is not very effective and is relatively expensive.

In conclusion the author says the most practical method of controlling yaws was (1) mass diagnosis and treatment, (2) followed immediately by permanent treatment dispensaries, (3) home visits by a yaws attendant. He regards the second as the most important, but previous mass treatment is essential to reduce the amount of yaws and to accustom the people to the necessity of adequate treatment. At the most successful dispensaries, with the aid of the local chief, 80-90 per cent of patients attended for 6 injections.

[This is an important paper and reports purposeful and careful work. It provides answers for most of the questions that should be considered before a yaws campaign is started. The expense, based upon existing costs, could be worked out from the data given.]

C J Hackell

REIN, C R, STERNBERG, T H, DWINELLE, J H & SHELDON, A J. Penicillin Therapy of Yaws and Serologic Results. *Arch Dermat & Syph* 1948, June, v 57, No 6, 942-51. [Refs in footnotes]

The material upon which this paper is based has been previously reported by DWINELLE *et al* [*this Bulletin*, 1948, v 45, 87]. The results of treatment in primary and secondary yaws in Haiti are considered from the results of Kahn reactions one year after treatment with 1,200,000 units of penicillin in watery solution or in arachis oil and wax.

The authors discuss the factors concerned in the reversal of positive serological tests in yaws as in syphilis. They are the stage of the disease, personal factors, initial serological titre, the sensitivity of serological technique, test used and treatment received. They say 'the serological response in yaws is

certainly much slower and less satisfactory than that observed in the treatment of early syphilis with a similar amount of penicillin." This may be due to the longer duration of the infections and the shorter period of observation in their patients.

Serological Results & Percentages

Treatment	Cure	Improvement	Relapse	Fastness	Cure and Improvement	Numbers of patients
In water in 4 days	23.1	68.7	4.8	1.5	93.8	200
In oil and wax in 2 days	11.0	81.9	5.5	1.5	92.4	151
In oil and wax in 1 day	6.4	83.4	4.8	2.4	92.8	149

The above table shows that more serological cures followed the longer course of treatment. Over 90 per cent. of cases had remained non-infectious (cure and improvement) throughout the year. [In the earlier paper referred to above it will be seen that clinical relapses are much fewer than serological relapses.]

The authors regard penicillin as probably the drug of choice in the treatment of yaws in the field as the course can be short, clinical results are good and serious untoward effects are absent.

In the discussion they report that therapeutic trials are being carried out in Haiti with 1,200,000 and 2,400,000 units of crystalline penicillin G in arachis oil and wax in 2 and 4-day ambulatory courses.

LEPROSY

IGNACIO CHALA H., J. Investigaciones terapéuticas en la lepra. Ensayos con Promin o Promanada. [The Treatment of Leprosy. Trial of Promin.] *Rev. Facul. de Med. Bogotá*, 1948 Oct. v. 17 No. 4: 121-59, 18 figs. English summary.

At the Lleras Acosta Institute Promin (or Promanada) has been tried for periods ranging between 7 months and 1 year and 8 months on 27 suffers from leprosy, only one of whom had had any previous treatment. Nineteen were of the lepromatous type, 7 the tuberculoid, and 6 the neuromatous type. The drug was given intravenously in doses of 2.5-3 gm. daily or on alternate days according to the general physique and condition of the patient. Frequent examinations of the blood were made but only slight changes were observed. Leprous reaction might occur during the course of treatment but disappeared if the drug was stopped and benadryl administered.

In the lepromatous patients improvement of the mucous and cutaneous lesions was observed in 58.25 per cent. [11 of the 19?] in the neuromatous type in 33.3 per cent. [presumably two patients] but none with peripheral nerve disturbance showed any benefit. The results generally were better in those in an early stage but before arriving the results it will be necessary to observe the patients for a long period and a real jumping to conclusion from early benefit in a few patients. Clinical details are given of all 27 patients and illustrations showing the condition before and after treatment.

H. H. Reid Scott

CHATTERJEE, S N Injection of Sulphetrone and Diasone in Leprosy a Preliminary Study *Internat Med Abstracts & Reviews* Calcutta 1949, Jan, v 5, No 1, 13-15

"1 Results of injecting sulphetrone and diasone, in small doses, in 17 cases are reported. A maximum of 5 cc of a 3.3 per cent solution has been used.

"2 Small doses of the drugs by injection, although not producing any appreciable blood level of the drug, produced clinical improvement without producing anemia.

"3 This method of treatment is considered more economical and safe than when the sulphone drugs are administered by mouth.

"4 It is suggested that more extensive trials should be undertaken to find out the minimum dose which will give satisfactory clinical and bacteriological results, without producing anemia or any other toxic symptoms."

HELMINTHIASIS

BARLOW, C H & MELENEY, H E A Voluntary Infection with *Schistosoma haematobium* *Amer J Trop Med* 1949, Jan, v 29, No 1, 79-87, 3 figs

There is no previous report of a voluntary human infection with *Schistosoma haematobium*. The senior author applied 8 cercariae of *S. haematobium* from 8 different specimens of *Bulinus truncatus* to his left forearm on 31st May 1944 in Egypt. He applied 8 other cercariae from the same snails to the umbilical region on 1st June 1944. On 14th June many cercariae from another 6 snails were applied to the right side of the umbilicus, and the following day some 147 small red papules were seen in this area, these were considered to represent the minimum of cercariae which had penetrated the skin. On 21st June cercariae from 16 snails were similarly applied, on the following day there were 61 more papules. It is therefore estimated that a minimum of 224 cercariae penetrated the skin at the four exposures.

Seventy-six days after the major exposure the temperature rose in the late evening, after slight sweating it had returned to normal by the following morning. Slight daily fever then persisted over several weeks without significant increase in severity. On the 77th day spermatozoa were seen in the urine, and 67 eggs were found in a specimen of seminal fluid. On the 78th day 79 eggs were recovered from a plug of mucus in the stool. On the 106th day eggs appeared in the urine. On the 139th day an itching nodule, half the size of a pea, appeared on the scrotum near the left groin, bloody serum discharged from this contained eggs of *S. haematobium*. Four or five less well-defined nodules were discovered on the scrotum. On the 149th day a nodule in the left groin was excised and found to contain eggs, in the excision wound was found a pair of adult *S. haematobium*. From the middle of the fourth month onwards eggs appeared in increasing numbers in the seminal fluid, faeces and urine, their numbers reached a peak in the seminal fluid at the end of the 6th month, in the faeces at the end of the 10th month, and in the urine between the 8th and 9th months, between 20,000 and 30,000 eggs then being passed daily in the latter.

The symptoms and signs steadily increased until by the 7th month the temperature rose in the evenings to a peak of 39.8 degrees Centigrade, and fell in the early morning after severe sweats to nearly normal. There was general weakness and prostration, blood and mucus appeared regularly in the stools, the urine, which contained blood, pus and shreds of mucosa, was passed frequently with associated tenesmus of the bladder and of the anus.

The patient was now confined to bed and he was unable to sleep without sedatives. By the end of the 7th month the infection had become chronic, the temperature did not rise above 37.6°C. and the general condition improved, the patient becoming ambulatory. The number of eggs in the seminal fluid markedly decreased, they were still numerous in the stools and in the urine, the latter containing up to 30 000 per day and much pus, blood, and shreds of mucus. Repeated differential counts between the 6th and 10th months showed an eosinophilia ranging from 6 to 16 per cent.

Ten months after infection an eight-day intramuscular course of treatment with Fouadin was begun, 47.5 ml. being given. This caused a rise in temperature with nausea and a persistent asthmatic cough. During treatment and for four days afterwards from 3 000 to 8 000 eggs were passed in the night urine; on the 5th day after treatment the number had fallen to 300 and the eggs passed were dead, no miracidia hatched from them after the 5th day. Fifteen days after completion of treatment the night urine contained only 22 eggs and two weeks later the seminal fluid contained only 9. Six weeks after the completion of treatment, and one year after infection, viable eggs again appeared in the urine. Fouadin treatment was again given and continued over a period of 19 days, 67 ml. being given on this occasion. Three months after completion of this second course viable eggs were again found in the urine and these persisted over a period of two months' observation. The patient was then treated with potassium antimony tartrate intravenously on alternate days for 24 days, to a total of 1.5 gm. of the drug. The treatment caused the rather severe side-effects commonly associated with it, but viable eggs ceased to appear after the 15th day of treatment. Urination was frequent and painful after treatment and pus and blood were still present in the urine. The urinary infection was cleared up by sulphonamide treatment. About this time there was evidence of coronary sclerosis and there was impairment of hearing; later signs of prostatic enlargement developed and this was dealt with surgically. Sections of the prostate tissue showed only a benign hypertrophy and no eggs were seen. No further evidence of the worm infestation has been found since the tartar emetic treatment.

The noteworthy features of this carefully observed infection, to which the authors direct attention, were the early appearance of eggs in the seminal fluid, their recovery from the scrotal skin and the demonstration of a pair of worms in a nodule there; the increase in egg production when the infection became chronic, and the failure of Fouadin to eradicate the infection. The hypertrophy of the prostate gland after parasitological cure with tartar emetic is held in part to be due to the previous infection. *A. R. D. Adams*

WATSON, J. M. Studies on Bilharziasis in Iraq. Part I. Present Status of the Subject. *J. Roy. Faculty of Med. of Iraq* 1948, July-Oct. v. 1., Nos. 4-5, 120-34.

The author surveys the information available on the subject of schistosomiasis in Iraq where it is widespread and serious, not only along the middle and lower Euphrates, but throughout the country except in the extreme north, and is likely to spread even more as the irrigation schemes are developed, unless adequate steps are taken to control it. The incidence cannot be stated exactly, but haematuria has been reported in up to 63 per cent of school children and in 100 per cent of patients in surgical ward of one hospital. Eggs have been found in 6 to 74 per cent of specimens of urine examined in various State hospitals. These figures may understate the true incidence.

The snail host, as in Egypt, *Bulinus truncatus* which find a favourable habitat in the shallow irrigation ditches with their weedy and sluggish water.

But there is a marked seasonal variation in the numbers of *B truncatus* found, they disappear in cold weather (November to May) and reappear in large numbers when the annual floods subside. The disease is very prevalent in the rice-field areas, and the snails, therefore, presumably inhabit those waters. No other snail is known to be a host in Iraq.

The author discusses possible campaigns to control the disease, but points out the need for much more detailed information on the ecology of *B truncatus* in Iraq before plans can effectively be made.

Charles Wilcocks

DEWHURST, K. E. The Tribal Distribution of Bilharzia in East Africa. *J Trop Med & Hyg* 1949, Mar, v 52, No 3, 60-61

In 1944, all African troops leaving Kenya for South East Asia were examined for schistosome ova. The author presents the results of examinations of fresh preparations of urinary deposits from members of different tribes in Kenya, Uganda, Tanganyika, Nyasaland and Northern Rhodesia. The total and the tribal results are shown in tables, in which the presence of *S haematobium* ova is recorded as positive and the finding of red cells and debris (but no ova) as "doubtful".

The territorial findings were as follows —

	Kenya	Uganda	Tangan- yika	Nyasa- land	Northern Rhodesia
Total examined	804	788	845	1,059	662
Total positive	10	10	53	158	94
Total doubtful	1	0	7	17	9
Percentage positive	1.2	1.2	6.2	14.9	14.6

The higher percentage of positive findings in the more southerly territories is noteworthy.

The territorial percentages are roughly reproduced in the individual tribal percentages, although the figures for the latter are mostly relatively small (in 22 out of 32 tribes the total number of men was less than 100). There was, however, some variation. It is noted, for example, that in Kenya, all 10 positive results came from 101 members of the Jalu tribe, in Tanganyika, the Makua and Mkwana (80 men each) showed 15 and 10 positives, respectively, in Nyasaland, 41 of 168 (24 per cent) Jao were positive and in N Rhodesia 25 of 76 (39 per cent) Chewa and 23 of 45 (51 per cent) Tumbuka. The other tribal percentages were fairly close to the averages for the territories to which the tribes belonged.

The author considers that the results give a rough estimate of the distribution of schistosomiasis in East Africa, but adds that it is somewhat conservative, since the subjects examined were young "healthy" Africans passed fit for military service.

H. J. O'D. Burke-Gaffney

BENNIE, I. R. Urinary Schistosomiasis: the Best Time to obtain Specimens, the Effect of Specific Therapy on Egg Output. *South African Med J* 1949, Feb 5, v 23, No 6, 97-100, 1 fig.

The excretion of eggs even in active *Schistosoma haematobium* infections is notoriously irregular. One hundred and twenty-eight African school children were found to be suffering from active urinary schistosomiasis on a single urine examination in November 1947; they were similarly re-examined in July 1948.

No specific treatment had been given but at the second examination only 95 (74.2 per cent.) were passing eggs. There have been various explanations for the irregular egg output and fluctuations in their numbers in the urine. In clinical practice it is usual to examine the terminal urine from the first emptying of the bladder on rising in the morning in the belief that eggs pass into the urine from the bladder during the night and their number is increased by distension of the bladder. Specimen of urine from a young male African suffering from *S. haematobium* infection, employed on domestic duties were subjected to carefully controlled egg counts each morning and afternoon for a month. From close observation of this patient it appeared that the number of eggs passed in the urine was closely related to the amount of physical exertion just before micturition, particularly if the exercise involved movement of the musculature of the lower abdomen. Examination of the early morning urine in this patient might well have failed to reveal the presence of urinary schistosomiasis but examination of the afternoon specimens invariably yielded eggs. The common practice of examining terminal urine from an early morning specimen should therefore be abandoned as reliance cannot be placed on examinations of urine from patients who are recumbent. Indeed, it is desirable to get patients to undertake exercise before passing urine when searching for schistosome eggs.

This same patient was treated with a single dose of Miracid D by the mouth daily for six consecutive days. The daily dosage ranged from 1 to 1.5 gm. and the total was 171.6 mgm. per kgm. On the second day the average output of eggs in the morning specimen rose, and there was a fall in that of the afternoon specimens. This was possibly due to the fact that the patient rested throughout the treatment but the increased morning output it is suggested may have been due to stimulation of the worms by Miracid D. The number of eggs in both specimens rapidly diminished thereafter and nine days after completion of treatment there were only a few blackened and calcified ova in the urine.

Toxic side-effects were loss of appetite, slight abdominal pain, severe headache and epistaxis, dizziness and weakness. These rapidly disappeared after completion of the treatment. There was some yellow staining of the skin of the palms and of the soles for about a week. A. R. D. Adams

BLAIR D. M. LOWTRIDGE F. G. MEESER C. V. & ROSS W. F. Urinary Schistosomiasis treated with Miracid D. *Lancet* 1949 Feb. 26 341-6

BLAIR *et al.* (1947) [this Bulletin 1948 v 45 526] have already recorded the disappointing therapeutic results of treatment of *S. haematobium* and *S. mansoni* infections in man with Miracid D given for two or three weeks in a daily dosage up to 4 mgm. per kgm. of body weight. Subsequently they found that a bigger daily dosage for a shorter period was effective in curing *S. haematobium* infections. They now report the results of oral treatment with Miracid D of 82 African children suffering from *S. haematobium* or *S. haematobium* and *S. mansoni* infections in Salisbury, S. Rhodesia. Daily doses of 15 mgm., 20 mgm. or 25 mgm. per kgm. of body weight were given by the mouth, the full amount, to the nearest 200 mgm. tablet was spread over five days in ten doses. The early results with the lower two dosages were so promising that the highest was later abandoned. All the children were re-examined over a period of twelve weeks after the completion of treatment. The results of treatment are set forth in a table. From this it is evident that of 53 children suffering from *S. haematobium* infection who completed the five-day treatment 47 were cured, that is no eggs whatsoever were found over the twelve-weeks period of observation and no active miracidia were found in the urine during this period. Four of the 53 were not cured in the

case of the remaining seven a few dead eggs were found. Twenty-nine other children, who were similarly affected, received the treatment over a period which approximated to the five-day course. The results of treatment in these cases were very similar. There were toxic side-effects in about half the children, these consisted of abdominal pain, loss of appetite, nausea, headache and dizziness, none was severe enough to cause a child to seek medical aid. As the lowest dose, 15 mgm per kgm daily, produced results at least as satisfactory in eradicating *S. haematobium* infections as the two higher dosages, there appears to be no purpose in exceeding it. Of 15 patients passing *S. mansoni* eggs in the stools, 13 were passing *S. haematobium* eggs in the urine, all 13 were cured of their *haematobium* infections by the course, but only 2 of the patients in this group ceased to pass *mansoni* eggs. Of the two patients with pure *mansoni* infections one was cured but the other was not. Thus of 15 patients with *S. mansoni* infection only 3 were cured, and this parasite would appear to be much more resistant than *S. haematobium* to Miracid D. The drug is expensive by African standards, the cost being about 8 shillings per patient, its advantages are that it can be given orally, and to ambulatory patients without skilled assistance or expensive equipment. [In a later note, in the *Lancet* of 12th March, Blair adds that of 74 children shewn to have been cured, after a 3-months follow-up, 51 have now been re-examined after 6 months. Of these, 1 is now passing live eggs, 12 are still passing blackened dead eggs and the remainder are not passing any eggs.] A R D Adams

RAIL, G A Intensive Treatment of Schistosomiasis with Sodium Antimonytartrate [Correspondence] *Lancet* 1949, Mar 26, 548

The author, writing from Gatooma, S Rhodesia, refers to the work of ALVES, ALVES and BLAIR and of GIRGIS AZIZ on the intensive treatment of schistosomiasis with antimony [this *Bulletin*, 1945, v 42, 815, 1946, v 43, 344, 752, 1948, v 45, 446]

He has treated 20 patients with a 30-hour course of sodium antimonyl tartrate in a dosage of 1 gram per 12 lb of body weight in six intravenous injections. In the first 6 cases, each dose was diluted in 10 ml of glucose saline, but later this was replaced by sterile water. Not less than 5 minutes was taken over each injection, the time being 10 minutes with the heavier doses. Half an hour before each injection, tincture of codeine (B P C) was given in a dose of 1 fluid drachm. This notably reduced irritant effects. The patients were confined to bed during the injections and for 12 hours afterwards. Before and during treatment they were encouraged to take large quantities of glucose. Diet was unrestricted and a high protein intake was encouraged.

In 10 cases in which ova had been found, they were absent six months after treatment. Two of these were negative after 8 months and two after 9 months.

Three patients showed no toxic reactions. 17 had slight headache, lassitude and inertia, but only 2 of them had severe reactions. One of these 2 patients had severe phlebalgia and vomiting during the second injection, and this necessitated splitting of the third injection of $2\frac{1}{2}$ grains into two (1 grain and $1\frac{1}{2}$ grains, respectively). He had no subsequent reactions. The second patient developed a severe conjunctivitis and peeling of the hands three days after completion of the course. These conditions cleared up in 10 days.

Desquamation was also seen in 4 other cases and conjunctivitis in 2. Cough developed in 9 cases, vomiting in 7, fever in 6 and erythema in 1. None of the more serious reactions (jaundice, haemorrhages or cardiac failure) was noted. The minor symptoms disappeared within 14 days, leaving many of the patients feeling better than they had for some years. The author suggests that the toxic effects are not so severe as might have been expected or had been feared by

Schistosomiasis has been reported in 138 *Assays* of some 10 provinces in China the most heavily infected area being round the three big lakes Taihu Tungtinghu and Poyanghu. On the basis of the incidence rate found in a large number of surveys (21 per cent.) an estimate may be made that there are over 5 million cases in China, but the author suspects that this would be an underestimate.

ii. In this paper the authors give a list of snail hosts of *S. japonicum* in China which contains 18 of the 17 named above. They state their reasons based on detailed work, for thinking that for separating these snails into species, a better basis must be found than radular formula, sculpturing or the colour of the shell. They summarize the paper as follows—

One hundred and forty-eight oncomelaniid snails known to be capable of transmitting oriental schistosomiasis which were collected from 7 villages near Soochow Wunsh, Kiangsu China, were subjected to individual observation regarding the number of whorl length and width, number of axial ribs for the last three whorls and denticle count of the radular tooth. It was found that the denticle count varies to such an extent that it is not a dependable criterion for separating species or genus in this group. The same conclusion is suggested for shell characters.

HOFMANN W. H. & GUTIERA, A. Distoma hepatico originando un absceso prencular [Fasciola hepatica originating in a Nucleo Abscess.] *Rev. Asoc. Med. Trop. y Parasit.* 1949 Jan. Feb., v 5, No. 1/2, 11-12.

Report of a case with the parasite in an abscess of the rectal muscle.

GALLIARD H. Infestation expérimentale par les larves plérocercoides de *Diphylobotrium mansonii* au Tonkin. (Experimental Infection by Plerocercoid Larvae of *Diphylobotrium mansonii* in a Parasit Humaine et Comparée 1948, r 23 Nov. 34 205-13 3 Figs. [17 refs.]

The site of penetration the migrations and the lesions caused by plerocercoid larvae of *D. mansonii* after being swallowed by a number of different experimental animals, were investigated by the author. The larvae used in the experiment were obtained from *Rana tigrina*, *R. limochanis* and *Tropidonotus piscator*.

Rana tigrina—Penetration took place through the stomach wall and was either direct and rapid or involved a resting period between the mucosa and the muscle layer where the larvae remained for as long as 20 days. Subsequently they were found in various internal organs before they ultimately made their way to the muscles. No lesions were produced by the passage of the worms.

Other batrachians and reptiles were also infected with ease but no reaction took place.

Guinea pig—Seven out of eight guinea pigs were successfully infected, and the larvae were found about 18 hours later on the external surface of the stomach wall. Penetration was not direct and there was a strong host tissue reaction in the form of ulceration and congestion. In an infection of 60 days duration the larvae in contact with visceral organs caused inflammatory reactions and adhesions. No intramuscular migration was observed.

Rat.—Twenty (300 hours after ingestion, three larvae were found in two rats in the pancreas, the stomach wall and free in the peritoneal cavity. In a third rat, 90 days after ingestion 25 larvae were recovered, in the stomach wall and on its surface on the liver and spleen and in muscle. No lesions or reactions resulted.

Rabbit.—After 17 hours 3 larvae were found on the stomach wall surface and 2 near the pancreas which caused haemorrhage. Invasion of musculature was observed in a rabbit 30 days after exposure.

Dog—Successful intestinal infections were obtained on feeding dogs with plerocercoids from *Rana tigrina*, from tadpoles of *R. limnocharis* and from *Tropidonotus piscator*, but single plerocercoids from the human eye failed to infect dogs

Cat—Ten plerocercoids were fed to a cat which showed eggs in the stools after 30 days, and after 79 days, 5 worms, 60 cm long, were recovered from the intestine. Another cat fed with 20 larvae produced 8 worms after 28 days

LANDELLS, J W Intra-Medullary Cyst of the Spinal Cord due to the Cestode *Multiceps multiceps* in the Coenurus Stage Report of a Case *J Clin Path* 1949, Feb, v 2, No 1, 61-3

A coenurus cyst, larval stage of the taeniid cestode *Multiceps multiceps* was removed from the spinal cord, at the level of the fifth and sixth thoracic segments, of a girl aged 14. She was suffering from spastic paraplegia of acute onset at the level of the sixth thoracic segment which was preceded by "pins and needles in the legs" of increasing intensity. The removal of the coenurus brought no improvement in the paralysis, but a second operation a month later revealed no more cysts nor visible cause for the paralysis. Ten months later there was slight sensory recovery but no motor recovery. The Casoni test was negative and there was no eosinophilia.

Comparative histological study of human brain material which had a similar infestation revealed that there is a natural line of cleavage between the cyst wall and the brain and that there is a reaction area about 3 mm deep in the latter, from the cyst wall outwards. This comprises four zones, of which the third or main zone of cellular infiltration is up to 700 μ in thickness. In the fourth zone there is evidence suggesting severe compression. It is observed that a corresponding zone of chronic granulomatous inflammation in the spinal cord would be of greater functional importance than in the brain and this would explain the non-recovery after removal of the cyst in the present instance.

Further helminthological details on the parasite, the first record of its kind from the human spinal cord, are provided, and illustrated by photomicrographs, [see also CRUZ, this *Bulletin*, 1949, v 46, 65] together with clinical details of another case of human coenurosis in England [*ibid*, 1942, v 39, 631]

FALLIS, A M *Ascaris lumbricoides* Infection in Guinea Pigs with special reference to Eosinophilia and Resistance *Canadian J Res Sect D Zool Sci* 1948, Oct, v 26, No 5 307-27, 20 figs (5 on 3 pls (2 coloured)) [15 refs]

"Clinical symptoms of *Ascaris* infection were produced in guineapigs by feeding several thousand eggs. Such infections caused a temporary loss in weight and severe congestion of the lungs but no elevation in temperature was observed. An eosinophilia was associated with infection and it reached higher levels following repeated infections. Injections of antigen caused a temporary rise in the number of eosinophiles. Guinea pigs developed a resistance

a result of infection. Some resistance was retained for at least 15 weeks following infection. A slight passive resistance resulted from injections of large quantities of serum from resistant animals and from injections of a liver extract prepared from resistant animals. The resistance was apparent from the amount of congestion in the lungs and the number and size of the larvae recovered from the lungs. The eosinophiles *per se* were not responsible for the resistance observed. It appeared that the body defences, in resistant animals, acted against the parasites before they reached the liver and more especially before they reached the lungs.

BUTTS, D. C. A. La infección filárica en Costa Rica. Contribución del Hospital de La Compañía Bananera de Costa Rica en Limón. [Filaria in Costa Rica.] *Rev. Med. Costa Rica* 1948 May, 3, 8 No. 169 103-8.

The city of Limón has a population between 10,000 and 15,000; the persons examined were distributed in four districts or perhaps we should say the area in which examinations were made was divided into four, namely the Port area, the Hospital zone, Jamaica Town and Cieneguita. Samples of blood were taken between 10 p.m. and 6 a.m., the majority between 10 p.m. and 2 a.m. Altogether 1,308 persons were examined. In Jamaica Town and Cieneguita 1,008 samples were taken from 269 persons and 101 specimens (the number of individuals is not stated) were positive for filarial embryos. Details of the other districts are not given but it is stated that the incidence on the Pacific coast was 1 per cent., that on the Atlantic coast 15 per cent. The age percentage of infestation is given as: Up to 10 years 18, 11-20 years 36, 21-40 years 36, 41-60 years 10 per cent., the youngest was 4 years, the oldest 55 years.

It is stated that the disease was originally imported from Jamaica and the West Indies. (It is not possible to say whether Jamaica was a focus of filaria many years ago but the abstractor while stationed for several years in the island examined many thousands of specimens of blood but found only four cases of filarial infection and all four were imported and were sent back home as soon as possible to avoid infection of others in the island.) The common mosquitoes in Costa Rica are *Aedes aegypti* and *Culex quinquefasciatus* (C. Jahgens) H. Harold Scott

OLIVER-GONZÁLEZ, J. SANTIAGO-STEVENSON, D. & MALONADO, J. F. Treatment of Filaria bancrofti with Hetrazan. Follow-up Observations Fifteen Months after Treatment. *J. Amer. Med. Ass.* 1949 Jan. 29, v. 139 No. 5 308-9.

At the end of 1947 the authors (this Bulletin 1948 v. 45 333) reported on the immediate results of administration of Hetrazan (1-diethyl-carbamyl-4-methylpyrazine) in 25 cases of *F. bancrofti* infection. The large majority of these cases were followed month by month for 15 months.

Of the original 25 patients 23 were seen at the end of 15 months. One patient only had any clinical symptoms during this period that might be attributed to filariae: he had a painful femoral gland and swelling of the upper third of the thigh, which subsided after a week.

Thirteen patients showed no microfilariae at the end of the period and of these 3 had shown microfilariae since the 10th month but only in insignificant numbers (1 to 4). The remaining ten patients showed 30, 19, 14, 11, 4, 4, 3, 1, 1, and 1 microfilariae respectively in 10 cm. of blood; all had lower a much larger number before treatment. These ten patients in whom the infection persisted were those to whom the lowest dosage had been given, although one had received a dosage of 4 mgm. per kgm. 3 times a day for 18 days (total

0.096 gm) the others had less than a total of 0.04 gm. The largest total dose given was 0.132 gm per kgm.

The authors conclude that Hetrazan given in adequate dosage to patients with *W. bancrofti* infection will clear the blood stream of microfilariae for periods of at least 15 months, and that there is no evidence of lymphatic disease that might be attributed to the filaricidal action of the drug. *L. E. Napier*

GORDON, R. M., CHWATT, L. J. & JONES, C. M. The Results of a Preliminary Entomological Survey of Loiasis at Kumba, British Cameroons, together with a Description of the Breeding-Places of the Vector and Suggestions for Future Research and possible Methods of Control. *Ann Trop Med & Parasit* 1948, Dec, v 42, Nos 3/4, 364-76, 1 map & 2 figs on pl.

This is an account of a brief survey of loiasis undertaken in June and July, 1948, at Kumba in the British Cameroons at the request of the Colonial Medical Research Committee.

The population of the township of Kumba consists of some thirty Europeans and about six thousand Africans. The Africans are mainly centred on a ridge 850 feet above sea-level between the rivers Kumba and Meme, the European residential quarters and certain public offices and institutions are set on nearby elevations. Streams run in the valleys between the occupied higher elevations, and the slopes of these valleys, as well as the stream-beds, are thickly overgrown with bush, small tributaries course down the slopes. The streams are generally brisk in flow with rocky bottoms, but in parts the flow is slow and the bottom is sandy with a mud covering overlaid in turn by decaying leaves.

In previous surveys, loiasis infection in the Africans varied from 3.7 to 9.0 per cent of children, and 16.5 to 23 per cent of adults, with microfilariae in the blood, the present survey shows that about 25 per cent of the Europeans had at one time or another shown evidence of infection, some of them being infected within less than twelve months of arrival. On the other hand, microfilariae have seldom been found in African children of less than seven years of age.

Available records and the authors' survey indicate that only *Chrysops silacea* and *C. dimidiata*, both known to be vectors of *Loa loa*, occur in the vicinity of Kumba, and that the former is apparently about 15-24 times more abundant. The observations recorded in this preliminary paper are concerned with *C. silacea* almost exclusively, the specific identity of the *Chrysops* larvae collected is, however, uncertain and requires further confirmation. *Chrysops* was biting from about 8.30 a.m. until after 4.30 p.m., occurring commonly indoors in dwellings at densities of from 0.3 to 1.0 fly per boy hour, the highest catches being in bungalows close to bush. Only female flies were seen despite repeated search in a variety of environments under different conditions for the male, high forest canopy was not examined although suspected as a possible haunt of the male. Man appears to be the chief host, and, probably secondarily, monkey, feeding was observed on the few cattle available, as well as on the usual small animals of the laboratory, there was no visual evidence in fly dissections of blood other than mammalian. Females captured in or near bungalows rarely showed any signs of advanced ovarian development (of 500 examined, 492 possessed immature ovaries or showed only slight development), there is other evidence that the females are not in the vicinity of dwellings in the phase when the ovaries are developing prior to oviposition. All of 19 flies examined particularly showed spermatozoa in the spermatheca.

Chrysops larvae, presumed to be *C. silacea*, were found in the streams but localized to the more stagnant parts and in the mud beneath the decaying

leaves. In the time available little work could be done on the breeding-out of larvae.

Infection rates for presumed *Loa loa* infections in *Chrysops* in three different surveys were 2 positive out of 32, 12.4 per cent positive out of 903 and 7.8 per cent with microfilariae (4.3 per cent. with infective forms) in 480 flies taken in bungalows in the present survey.

It is estimated that a European is liable to infection at least once in five days. The infection rate in Europeans and in Africans is less therefore than might be expected. Three explanations are put forward and briefly discussed. These are as follows:—(1) Infective larvae do not always successfully penetrate into the human skin. (2) Many persons develop an immunity to further infection after earlier unobserved or non-patent infections (this is discounted as unlikely). (3) the absence of microfilariae is due to unisexual infections, failure of worms to mate or chance absence of the microfilariae in the blood on the occasion of the blood film examination. This third point of view is supported not only by studies on animal filariasis but also by histories of Calabar swellings or migrating adult *Loa loa* in persons with negative blood films.

The possibility of control measures is reviewed tentatively.

Chrysops larval control.—There seem to be good prospects of satisfactory if not complete control of the localized breeding places by clearing bush and canalisation, the effectiveness of insecticides should, however, be investigated. The possibility of increased facility for anopheline breeding must be borne in mind.

Protection of the individual—Screening of at least one dayroom per bungalow is suggested. Wide mesh netting soaked in 60 per cent dimethyl phthalate (DMP), if used as for a window-screen is shown to be ineffective as a barrier to *Chrysops*. Flies were effectively repelled for four hours when a 60 per cent DMP preparation ("Liquid Mylol") was applied to exposed skin. "Mylol Cream" containing 30 per cent DMP was ineffective. Clearing of bush from around bungalows seems likely to diminish the fly density in their vicinity.

A final section on future research is not readily summarized and should be consulted in the original. The many aspects of entomology and helminthology mentioned are indicative of our present paucity of knowledge on loiasis. The Kumba area is recommended as an ideal centre for further intensive studies on this disease and its control.

NETTEL F., R. Contribución al estudio de las condiciones naturales de las zonas de oncocercosis en Chiapas. [*Oncocercosis in Chiapas, Mexico.*] *Medicina Mexico* 1949 Jan. 25 v. 29 No. 572 "1 32 7 figs. 16 refs.] English summary

Oncocercosis in South Chiapas is largely confined to the high levels. In one village 1,000 metres above sea-level with only 400 inhabitants, 65 per cent. were infected. Here the rainfall is heavy 320 cm. a year and rain fell on 181 days. At another focus in the north, where the disease is also prevalent though less than in the former, the southern focus the rainfall is 80-160 cm. on 31-60 days in the year.

Captures of Simuliidae were made during one hour in the morning (7-8 a.m.) and one hour in the afternoon (4-5 p.m.) during the wet season (April-September 1946 and 11,657 were caught. Of these 10,294 (88.3 per cent.) were *S. ochraceum* 853 (8.4) *S. calidum* and 378 (3.7) *S. mutabilem*. Though patients come down to the lower levels they do not transmit infection because *S. ochraceum* is not found there.

H. Harold Scott

MAZZOTTI, L Estudio acerca del tratamiento de la oncocercosis [On the Treatment of Onchocerciasis] *Medicina Mexico* 1949, Jan 10, v 29, No 571, 1-5

After a few remarks on the use of the chloride of 1-diethylcarbamyl-4-methylpiperazine, or Hetrazan, in filariasis in general, the author records its use in onchocerciasis. The drug produces more severe reactions in this infestation than it does in infestation by *W bancrofti*, so smaller doses are given, starting with 2 mgm per kilo bodyweight, thrice daily by mouth, and increasing to 4 mgm, but limiting the course to seven days.

He has treated in this way 65 patients and has observed 36 of them during a period of 1-14 months. In all of them there was a diminution in the number of cutaneous embryos found, in some to such a degree that they could be discovered only with difficulty. The adults in the nodules showed an "altered vitality". After 4-8 months in some cases the embryos were again becoming present in larger numbers and it was noticed that these were all in patients with nodules which had not been extirpated.

In the cases of seven patients observed for 6-14 months, five had remained free, and two were showing cutaneous embryos again. The eye symptoms cleared rapidly and the microfilariae disappeared "in a few days". In this regard, of seven patients under observation for 10 months, in one only had the embryos reappeared in the eyes.

H Harold Scott

VARGAS, L Control de la oncocerciasis [Control of Onchocerciasis] *Bol Oficina Sanitaria Panamericana* 1948, Dec, v 27, No 12, 1150-59
English summary

This paper summarizes the principal features of onchocerciasis as it is found in the New World. The author begins by stating the primary requisites for the control of any disease: sufficient funds, organization, enough patients and susceptible people who are interested in the control of the disease and lastly a favourable environment for the work. Control may then be started (a) if the incidence of the disease is sufficiently high, and (b) if there is an appreciable death rate. The incidence of onchocerciasis is not always easy to elucidate and unless similar methods are employed the results of different surveys may not be comparable. The best diagnostic procedure is to observe the following: (1) skin biopsy, (2) eye lesions, (3) allergic phenomenon, (4) eosinophilia. The transmission quotient of onchocerciasis is defined as the proportion of 100 individuals who receive an infecting bite in a given period of time. Evidence of infection is absent in children under 1 year, it becomes manifest in early life and reaches a maximum before maturity.

The three vectors of the disease in Central America are *Simulium ochraceum*, *S callidum* and *S metallicum*. These produce a maximum of 5 generations in the season which lasts from October till the end of March. Anti-larval control by DDT or 'Gammexane' during the dry season is recommended as the best way of getting rid of the disease.

DEFICIENCY DISEASES

MAINZER F Menstrual Disorders in Pellagra *Acta Med Scandinavica* 1949, Jan 20, v 132 No 4, 384-91 [46 refs]

Amongst 11 women of childbearing age, suffering from pellagra, menstruation was normal in only one patient. Amenorrhoea was present in 3

by the author as 30 per cent] This fact was used by the author as a rough test for the presence of the "salt" {Apparently he bases his percentage of 17 per cent (*vs supra*) on this test.]

The author injected normal O-group blood into four patients with the disease. The survival time was "about 100 days which is the figure given for their survival in normal recipients. From this he concludes that the increased haemolysis is due to the abnormality of the cells.

Transfusion was the most promising treatment. This had to be repeated frequently. [See this Bulletin 1947 v 44 344] L. E. Nafziger

VENOMS AND ANTIVENENES

GOYAL, R. K. An Investigation into the In Vitro Titration of Cobra and Dabola Antivenins. *Amer J Trop Med* 1948 Sept. v 23 No 5 711-20

The author reports the failure (except in the case of dabola antihæmolysin) of attempts to correlate various *in vitro* titrations of cobra and dabola antivenins with *in vivo* tests. He finds that the neurotoxic fraction of cobra venom is more important than the hæmolysin from which it can be separated by alkalisation of dilute venom. Titration of antivenin was attempted by observing the action of mixtures of neurotoxin plus antivenin on cultures of *Paramecium caudatum* and by certain other tests including flocculation and complement fixation. No satisfactory correlation between *in vitro* and *in vivo* results was obtained, possibly because there is some interaction between the anti hæmolysin and antineurotoxin which interfered with the interaction of the neurotoxin with its corresponding antibodies.

The author's attempts to fractionate dabola venom failed. Fractions containing the hæmolysin were isolated without difficulty but there was no evidence of non hæmolytic toxic fractions. *In vitro* titration of dabola hæmolysin (goat erythrocytes plus egg yolk) gave results roughly parallel to those of *in vivo* tests and the author suggests that such antihæmolysin titrations in the case of dabola antivenin might be used for preliminary tests before final *in vivo* titration is undertaken. B. G. Margrafs

WU, Y. K. & TSI, Y. H. Poisonous Snake Bite. A Report of Four Cases from the Chungking Area. *Chinese Med J* Chengtu Edition. 1945 Apr v 63A No 3 148-51

Four cases of snake-bite are reported, but the snake inflicting the injury was identified in one of them only. It was *Tropidophis mucronatus*. The symptoms in all four patients were very similar both in character and in degree, and this is a common poisonous snake in Szechuan and parts of south-east China so it was probably the cause in others also. In spite of intense local pain—two of the patients were bitten on the foot, one on the leg and one on the hand—extensive swelling of the whole limb, oedema, ecchymosis and blister formation around the site bitten, the systemic disturbance was remarkably slight. This is ascribed to the probability of the mildness of the venom of the snake in this district rather than to the amount of the venom injected being small. Antivenin it is stated, is generally not available in this country and the treatment consisted of the application of tourniquets, one near above the bite and another higher up the limb with loosening for 5 minutes at hourly intervals and incisions and potassium permanganate locally. H. Harold Scott

KOSZALKA, M F Multiple Bee Stings with Hemoglobinuria and Recovery
Report of a Case *Bull U S Army Med Dept* 1949, Mar, v 9, No 3,
212-17 [Refs in footnotes]

"An unusual case of multiple bee stings of all exposed parts of the body, with severe edema, hemoglobinuria and subsequent recovery, is reported. The severity of the injuries and reaction might have been lessened had it been possible to extract the stings immediately after their deposition into the skin, since the sting apparatus when left in the skin continues to force out the contained venom by muscular action. The rapid recovery of this patient is attributed primarily to the parenteral use of calcium gluconate. Calcium salts apparently lessen the phenomenon of transudation, inhibit smooth muscle spasm, and neutralize the toxic effect of the bee venom. Its use, therefore, is suggested in the treatment of stings of bees and other insects where epinephrine has failed to effect a satisfactory response. The newer antihistaminic drugs, not available at the time, are also worthy of trial."

ROMAÑA, C & ABALOS, J W *Latrodectus mactans*, su combate [Control of *Latrodectus mactans*] *An Inst Med Regional Tucuman, Argentina* 1948, Dec, v 2, No 2, 153-61, 2 figs

The English summary appended to the paper is as follows —

"The authors refer to the domiciliary habits of *Latrodectus mactans*, in the Americas and Hawaii, and to the control by physical and biological means

"They refer to their own experiences with different products, and arrive at the conclusion that 'Gammexane' is the most effective toxic for the fight against *Latrodectus*. For a successful control it is sufficient to treat houses and outdoor buildings, which are the places where accidents are more frequent."

DERMATOLOGY AND FUNGUS DISEASES

PIERS, F Sunlight and Skin Cancer in Kenya *Brit J Dermat & Syph* 1948, Oct, v 60, No 10, 319-32, 3 figs [24 refs]

In the author's opinion sunlight is a paramount factor in the causation of cutaneous cancer in Kenya. He distinguishes three types of cutaneous response to prolonged exposure to sunlight:

(1) *Permanent suntan*: the commonest reaction, results in thickening and coarsening of the skin, permanent hyperaemia sometimes occurs and there is usually intensive pigmentation. The pigment is either diffuse or persists in the form of permanent freckles.

(2) *Farmer's skin*, in which the main characteristic is an accentuation of the normal skin folds, particularly at the back of the neck where a system of rhomboid furrows results known as *cutis rhomboidalis nuchae*. Microscopically degeneration of the elastic and collagen fibres of the corium can be seen.

(3) *Chronic solar dermatitis*. This, the most advanced stage of chronic sunburn, results in thinning of the epidermis, patchy pigmentation, telangiectasis and abnormal keratinization indicated by persistent desquamation or the formation of keratoses.

Whereas diffuse changes, as in farmer's skin and permanent sun tan do not favour the development of cancers, the more proliferative localized lesions in chronic solar dermatitis are the immediate forerunners of malignant changes.

the pus and shown to be pathogenic for white mice and a rat but not for guinea-pigs was identified as *Cephalosporium acremonium*. The disease responded to the administration of iodine (intramuscular injection of Lipiodol¹) for three months supplemented by sulphonamide therapy during one week of the period.

As a background to this case (previously noted by COCTELEX & COCRET *C.R. Soc Biol* 1915 v 129 36² and here described in detail) the authors provide a comprehensive and useful survey of the association of species of *Cephalosporium* with pathological conditions in man. The published records are reviewed and tabulated under three heads—mycetomas and other deep-seated infections, superficial cutaneous infections and infection of mucous membranes—and the geographical distribution is noted. Seventeen species of *Cephalosporium* and two of *Hyalosporium* (probably a synonym of *Cephalosporium*) claimed to have been implicated in these conditions are listed. Most of these forms have been inadequately described and are of very doubtful status but *C. acremonium*, the type species of the genus which has been isolated on a number of occasions merits recognition as a human pathogen.

MISCELLANEOUS DISEASES

GORDON J. E. & AUGUSTINE D. L. Tropical Environment and Communicable Disease. *Amer J Med Sci* 1948 Sept. v 216 No 3 343-57 [89 refs.]

The general purpose of this essay is to stress the idea that the proper study of disease in hot climates involves study of the host, the parasite (if there is one) and all the other features of the environment. The authors are concerned to show that small environmental variations determine the presence or absence of disease. Of the environmental factors climate is perhaps the most important since it not only exerts a direct effect on man, but it determines the biological environment which is so closely associated with the transmission of disease. But all the environmental factors react on each other and the study of the whole environment is necessary both for the individual patient and for people in the mass. The authors treat the subject on broad lines and point out some of the gaps in our knowledge.

Charles H. Fulcocks

LEÓN L. A. El clima y las enfermedades tropicales del altiplano ecuatoriano. [Climate and Tropical Diseases of the Upper Levels of Ecuador.] *Rev Asoc Med Trop y Parasit* 1919 Jan. I b v 5 Nos. 1/2, 4-8, 4 figs.

Ecuador, a small country on the Pacific Coast of South America, may for descriptive purposes be divided into three zones. Littoral, the inter Andean region (upper level) and the Eastern region. The second of these is the subject of this contribution. It is very mountainous, with interspersed valleys and, consequently with varied temperatures and climate—torrid, temperate and cold. There are parts where the average temperature is from 76° to 20°C., and there may be daily variation up to 15°C.

The diseases of the country are divided by the author into 5 groups: (i) Those met with all over the area, notably smallpox, the enteric fever typhus and infantile paralysis. (ii) Those endemic in the mountains—amœbiasis and helminthic infestations, pediculosis and mycotic skin affections. In this section only of the paper are there any figures of prevalence given. Of 1,743 school-children examined in the towns of Quito, Otavalo and Tulcan

24.29 per cent were passing cysts or trophozoites of *E. histolytica*, as were 28.27 per cent of 902 children in various rural schools. Among urban scholars ascariasis is the commonest helminthic infestation, 30.6 per cent, *Trichuris* in 6.5, *Hymenolepis* in 6.3 per cent. In rural school-children 69.8 per cent had *Ascaris*, 38.5 *Trichuris*, 1 per cent *Taenia* and 0.7 per cent *Hymenolepis*. Common mycotic affections are by *Microsporon audouinii*, *M. lanosum*, *M. album*, *Achorion schoenleinii*, *Trichophyton gypsum*, *T. radiolatum*, *T. meuum* and *Pityriasis versicolor*. (iii) Diseases endemic or epidemic in the northern sector only. *Rabies* has been becoming more frequent since 1942, especially among the Indians who live in close contact with their dogs. *Plague* occurs in outbreaks, especially in the towns of Alausi, Riobamba and Ambato, often preceded by epizootics among hares and guinea-pigs (*Cavia aperea*). *Xenopsylla cheopis* is the chief vector, but *Pulex irritans* also transmits in mountainous districts. Other ectoparasites such as *Ceratophyllus londinensis* and *Leptopsylla musculi* on rats and mice, and *Rhopalosylla cavicola* and *Hectopsylla suarezi* on guinea-pigs, it is said, play no part in plague transmission. (iv) Endemic diseases in the valleys are *bartonellosis*, *pinta* (in four foci, the valleys of Chillos, Yunguilla, Catamayo and Malacatos), *leprosy*, *malaria* with *A. pseudo-punctipennis* as the chief vector, but *A. albimanus* is also present. A few cases of *balantidiosis* are seen. (v) Sporadic diseases. Cases have been reported of *bacillary dysentery*, *brucellosis*, *Weil's disease*, *filariasis*, *echinococcus*, *Dipylidium* infestation, intestinal *coccidiosis*, cervicofacial *actinomycosis* and *chromoblastomycosis*.

Other diseases are mentioned as occurring in other parts of Ecuador, but not in the district which is the subject of this paper. These are dengue, relapsing fever, Chagas's disease, yaws, hookworm and maduromycosis. [Unfortunately no figures of incidence are given except for the few mentioned in group ii.]

H. Harold Scott

GELFAND, M. A Few of the Rarer Diseases seen in Africa. *East African Med J* 1948, Dec., v 25, No 12, 447-53

Onyala is the African name given to a peculiar bleeding disease first described in Angola in 1904. It was reported in Southern Rhodesia, where it is common, by MORRIS in 1926 and later by BLACKIE [this *Bulletin*, 1938, v 35, 74], who showed that the condition was associated with a marked thrombocytopenia. Gilkes in 1934 gave an accurate account of the disease in Northern Rhodesia [*ibid.*, 1934, v 31, 751]. A number of workers (including Morris) have found that intramuscular injection of blood from any healthy adult stopped the bleeding, but blood transfusion may be necessary in severe cases. Vitamin K has been given with poor results.

The disease is usually found in an area extending from Broken Hill in the North to Angola in the West, to the eastern boundary of Southern Rhodesia (Nyasaland practically escaping) and southwards to the Transvaal and Bechuanaland. It has occasionally been reported as common in East and West Africa and the Congo. There is no evidence of any toxic factor in the diet or in remedies given by witch doctors or herbalists. The disease is most common in adult males, but is found at all ages and in females.

The characteristic lesion distinguishing *onyala* from Werlhof's purpura (essential thrombocytopenia) appears to be the blood blister. The illness starts abruptly, the first symptom usually being bleeding from the mouth or nose, which may be mild or severe. Sooner or later bleeding occurs into the urinary tract, not uncommonly into the bowel, and in females into the vagina. Typically a blister varying from $\frac{1}{4}$ to $\frac{3}{4}$ of an inch in diameter is found anywhere on the mucosa of the lips, oral cavity, tongue or pharynx, such blisters are

the pus and shown to be pathogenic for white mice and a rat but not for guinea-pigs was identified as *Cephalosporium acremonium*. The disease responded to the administration of iodine (intramuscular injection of "Lipiodol") for three months supplemented by sulphonamide therapy during one week of the period.

As a background to this case (previously noted by COUTELLE & COCHET C.R. Soc. Biol. 1945 v 129 392, and here described in detail) the authors provide a comprehensive and useful survey of the association of species of *Cephalosporium* with pathological conditions in man. The published records are reviewed and tabulated under three heads: mycetomas and other deep-seated infections; superficial cutaneous infections; and infection of mucous membranes—and the geographical distribution is noted. Seventeen species of *Cephalosporium* and two of *Hyalospor* (probably a synonym of *Cephalosporium*) claimed to have been implicated in these conditions are listed. Most of these forms have been inadequately described and are of very doubtful status but *C. acremonium*, the type species of the genus which has been isolated on a number of occasions merits recognition as a human pathogen.

MISCELLANEOUS DISEASES

GORDON J. E. & AUGUSTINE D. L. Tropical Environment and Communicable Diseases. *Amer J Med Sci* 1948 Sept., v 216, No 3 343-57 [93 refs.]

The general purpose of this essay is to stress the idea that the proper study of disease in hot climates involves study of the host, the parasite (if there is one) and all the other features of the environment. The authors are concerned to show that small environmental variations determine the presence or absence of disease. Of the environmental factors climate is perhaps the most important, since it not only exerts a direct effect on man but it determines the biological environment which is so closely associated with the transmission of disease. But all the environmental factors react on each other and the study of the whole environment is necessary both for the individual patient and for people in the mass. The authors treat the subject on broad lines and point out some of the gaps in our knowledge.

LEÓN L. A. El clima y las enfermedades tropicales del altiplano ecuatoriano (Climate and Tropical Diseases of the Upper Levels of Ecuador). *Rev Asoc Med Trop y Parasit* 1949 Jan. Feb., v 3 Nos. 1/2, 4-8, 4 figs.

Ecuador, a small country on the Pacific Coast of South America, may for descriptive purposes be divided into three zones: Littoral, the inter Andine region (upper level) and the Eastern region. The second of these is the subject of this contribution. It is very mountainous with interspersed valleys and, consequently, with varied temperatures and climate—torrid, temperate and cold. There are parts where the average temperature is from 7-6° to 20°C. and there may be daily variation up to 18°C.

The diseases of the country are divided by the author into 5 groups: (1) Those met with all over the area notably: smallpox, the enteric fevers, typhus and infantile paralysis. (2) Those endemic in the mountains—amobiasis and helminthic infestations, pediculosis and mycotic skin affections. In this section only of the paper are there any figures (prevalence given). Of 1,745 school-children examined in the towns of Quito, Otavalo and Tulcan

between symmetrical gangrene of the extremities and tropical phlebitis? He doubts the latter, as tropical phlebitis is always unilateral to begin with. Treatment is not discussed [See also this *Bulletin*, 1948, v 45, 545]

GELFAND, M Tropical Primary Phlebitis Thrombophlebitis With some Remarks on its Clinical Features and Treatment *South African Med J* 1949, Feb 19, v 23, No 8, 129-32, 6 figs

In this paper Gelfand carries the study of tropical thrombophlebitis a stage further by suggesting that in addition to the affection of the vein there is spasm of the corresponding artery, and that this is the cause of the oedema which is so striking a feature of the disease. He shows that in pure venous thrombosis there is little or no oedema, no tenderness, little or no fever, and a great liability to embolism. In thrombophlebitis such as has been described in Africans, on the other hand, there is primary inflammation of the vein, with pain, fever, oedema and little tendency to embolism.

On this assumption he has treated five cases (in which the femoral vein was affected) by injection of planocaine into the lumbar sympathetic ganglia of the side corresponding to the inflamed vessel, with the object of eliminating spasm. The results were good. The technique was as follows —

"Ten c.c. of a 2.5% planocaine solution was injected 2 inches from the midline of the affected side towards each of the lower four lumbar vertebrae. A lumbar puncture needle was used. The needle was directed towards the body of each vertebra. On striking the bone, the needle was withdrawn slightly and carried forward into the tissues just beyond the vertebra."

The author thinks that some of the cases of gangrene which have been described in Africans may have been the result of a similar process of arterial spasm.

He records a case of thrombophlebitis of both external jugular veins, in which the oedema of the face resembled that produced by nephritis.

For references to other papers on tropical thrombophlebitis, see the abstract on an earlier paper by Gelfand, above.

Charles Wilcocks

DAVIES, J N P Pathology of Central African Natives Mulago Hospital Post Mortem Studies IX *East African Med J* 1948, Dec, v 25, No 12, 454-67 [26 refs]

This paper in the series [this *Bulletin*, 1948, v 45, 1118, 1949, v 46, 90] deals with cardio-vascular conditions. Congestive heart failure was found 229 times in 3,705 autopsies, which is probably an underestimate. In 5 per cent of these, no adequate cause was found.

Hypertensive renal disease accounted for 31 per cent and aortic syphilis for 20.9 per cent, this being commonest between the ages of 30 and 40 (25 cases) and renal disease between 20 and 30 (23 cases). [In the absence of birth certificates in all cases the ages cannot be quite accurate.] In 2,994 autopsies, evidence of rheumatic carditis was found in only 22 cases, mitral stenosis being present in 21 of these. Subacute bacterial endocarditis was uncommon.

Acute bacterial endocarditis was common and found in 2.5 per cent of all autopsies, the majority of cases arising from a primary septicaemia, the next common cause being pneumonia, and then a *Neisseria* infection. The most common single valve affected was the aortic (35 cases), while the aortic and mitral valves together were involved in 12 instances. In only 3 cases had the valves been previously damaged by rheumatism.

black, and tend to rupture leaving a painful ulcer. The ulcers are often multiple, the tongue enlarges and the parotids may swell. In about a third of the cases the blisters occur on the legs, forearms, hands and occasionally the trunk. Almost always purpuric spots are seen on the conjunctivæ and sometimes on the skin.

The course is usually short, but there is always the risk of a relapse. Some cases are severe from the start and haemorrhage is serious, while in others who are apparently progressing favourably bleeding recurs with increased violence. The most serious type is probably that in which intracranial haemorrhage develops, the patient passing into coma with focal signs and the fluid on lumbar puncture being blood-stained.

Primary splenic abscess was first described by WALLACE at Broken Hill in 1922 (this Bulletin 1922, v 19 816) where there was an outbreak of some 40 cases in a comparatively short time. Although autopsies were performed in a number of cases no common aetiology was found and blood cultures from several patients were negative. Wallace concluded that the abscess was caused by a thrombosis of the splenic vein leading to a liquefactive necrosis of the organ which had become secondarily infected, probably with gas-producing organisms from the bowel. He found that a number of patients had a femoral thrombosis. A tympanitic splenic tumour was very suggestive of the condition. The condition is usually seen in young adults starting abruptly with fever and pain in the left hypochondrium. The swelling rapidly enlarges upwards as well as downwards, raising the left dome of the diaphragm and encroaching on the lung. Dullness may be found at the left base, the signs then closely resembling pneumonia or empyema, while the heart may be rotated upwards and to the right. This condition is best shown radiologically. A tympanitic note over a splenic tumour is very suspicious.

If such a condition is suspected, diagnostic aspiration should be performed at once. The pus is fluid, of a reddish colour, often frothy and sterile on culture. Treatment so far has been by drainage but a discharging sinus persists for many months. Removal of the spleen has not been attempted. There is insufficient evidence to incriminate amoebiasis, emetine has no effect.

This type of abscess is common in the Rhodesias, but so far as the author knows is not met with in East Africa.

Thrombophlebitis or tropical phlebitis has been recently reported in East Africa (this Bulletin 1948, v 43 1186) but was first described in 1911 by FISHER in Northern Rhodesia (this Bulletin 1912, v 39 199). The onset is sudden, usually with high fever, shivering and headache. The duration of the fever usually accompanied by a leucocytosis, varies from a few days to as long as ten weeks, and the patient in severe cases may be seriously ill and delirious. Pain in the affected vein with oedema of the extremities, begins at the start and usually enables a diagnosis to be made. The peripheral veins usually attacked are the femoral—less frequently the subclavian, axillary and external jugular. When the lower limb is involved a permanent swelling of varying degree may persist, but emboli rarely occur.

The prognosis as regards life is good when superficial veins only are involved, but is usually grave when the larger internal ones (e.g. the mesenteric, portal and cavernous sinus) are attacked. In cases of mesenteric occlusion passage of blood *per rectum* is an important sign and the illness may closely simulate dysentery. Pain is usually severe. In thrombophlebitis, in which there is inflammation of the vein with secondary clot formation, oedema is characteristic, and it has been shown that this is due to an arterial spasm occurring simultaneously which disappears rapidly after lumbo-sympathetic block.

The author raises two points—(1) Can primary splenic abscess be included in the same category as tropical phlebitis? (2) Is there any relationship

between symmetrical gangrene of the extremities and tropical phlebitis? He doubts the latter, as tropical phlebitis is always unilateral to begin with. Treatment is not discussed [See also this *Bulletin*, 1948, v 45, 545]

DAVIES, J N P **Pathology of Central African Natives** *Mulago Hospital Post Mortem Studies IX* *East African Med J* 1948, Dec, v 25, No 12, 454-67 [26 refs]

This paper in the series [this *Bulletin*, 1948, v 45, 1118, 1949, v 46, 90] deals with cardio-vascular conditions. Congestive heart failure was found 229 times in 3,705 autopsies, which is probably an underestimate. In 5 per cent of these, no adequate cause was found. Hypertensive renal disease accounted for 31 per cent and aortic syphilis for 20.9 per cent, this being commonest between the ages of 30 and 40 (25 cases) and renal disease between 20 and 30 (23 cases). [In the absence of birth certificates in all cases the ages cannot be quite accurate.] In 2,994 autopsies, evidence of rheumatic carditis was found in only 22 cases, mitral stenosis being present in 21 of these. Subacute bacterial endocarditis was uncommon. Acute bacterial endocarditis was common and found in 2.5 per cent of all autopsies, the majority of cases arising from a primary septicaemia. The next common cause being pneumonia, and then a *Neisseria* infection. The most common single valve affected was the aortic (35 cases), while the aortic and mitral valves together were involved in 12 instances. In only 3 cases had the valves been previously damaged by rheumatism.

The only previous reference to the condition known as endocardial fibrosis is by BEDFORD and KONSTAM (*Brit. Heart J.* 1948 v 8 236) who noted it in a number of West African soldiers dying of congestive heart failure. This condition is common at Malaga and typically the lesion consists of fibrosis of the endocardium, often extending deep into the myocardium. The coronary arteries appear normal. The aetiology is obscure. It is not of syphilitic origin and the fibrosis is not usually accompanied by cellular infiltration. These cases show a very chronic type of congestive heart failure: murmurs of valvular incompetence are found, and a pericardial effusion is often present. On opening the heart which is usually dilated, it is found that the endocardium, especially at the apex of the left ventricle is thick and pearly white in colour with strands of fibrous tissue going deep into the myocardium. The fibrosis extends up the ventricular walls and as a result the mitral valve is pulled down and distorted, but the aortic valve is rarely affected. Of the last 43 cases of congestive heart failure seen at autopsy 8 have shown this lesion: these cases having formerly been grouped as syphilitic myocarditis on insufficient evidence. Myocarditis, endocardial necrosis and endocardial fibrosis are important in the pathology of the African but their aetiology is very obscure and they are not usually associated with any of the common cardiac diseases.

Cardiovascular syphilis has been previously dealt with in relation to the problem of syphilis in Uganda (*this Bulletin* 1948, v 45 544). Very little is known about congenital heart disease in Africans.

BECKER in South Africa found that arterio-sclerosis was the direct cause of death in 0.4 per cent. of autopsies. At Malaga minor degrees of atherosclerosis of the aorta were common while in 33 cases out of 2,994 autopsies an advanced degree of this condition was found. Coronary thrombosis was rare in Africans, as was heart failure due to hyperthyroidism.

WILLIAMS (*ibid* 1942, v 39 417 *Bulletin of Hygiene* 1945 v 20 200) concluded that hypertension, both "essential" and renal is common in Uganda but that chronic nephritis and urethral stricture accounted for the majority of cases of high blood pressure. At Kampala, hypertensive disease is the commonest cause of congestive heart failure: hypertrophy due to this condition being very frequent at autopsy. Renal conditions are fully discussed, and it is considered that nephritis and, less commonly renal obstructive lesions are the commonest cause of hypertensive heart failure.

Miscellaneous cardio-vascular lesions including periarteritis nodosa Buerger's disease (thrombo-angiitis obliterans) have been found at autopsy while peripheral gangrene often symmetrical, is sometimes seen. Thrombophlebitis is not uncommon but pulmonary embolism is rare. [Is this because the African usually *likes to stay quiet for long?*] Raynaud's syndrome and cardiac aneurysm have not been met with.

Purulent pericarditis has been described in a previous paper. Pericardial effusions are sometimes seen in cases of endocardial fibrosis. No case of rheumatic pericarditis was seen nor of pericarditis associated with valvular lesions, and in no case with rheumatic valvular lesions was there evidence of past pericarditis. There were 45 instances of tuberculous pericarditis in 429 cases of tuberculous and pericardial disease was found on 105 occasions in 2,994 autopsies.

The commonest valvular lesions seen at autopsy were—aortic val. v 208 cases (syphilitic 167 bacterial endocarditis 35) mitral valve 33 (bacterial endocarditis 13 rheumatism 21).

Degenerative cardio-vascular lesions, atherosclerosis coronary thrombosis and primary hypertension appear less frequent in East than in South Africa, but it must be remembered that the majority of autopsies at Malaga are in patients under 40 years of age and there is no evidence to suggest that in the older African

the incidence of degenerative changes is less than in the European [The expectation of life is less in the former than the latter] In the last two years, two conditions hitherto overlooked, viz, symmetrical gangrene of the extremities [GELEAND, thus *Bulletin*, 1947, v 44, 937] and endocardial fibrosis, have been described

SOYSA, E The Eosinophilic Respiratory Syndrome A Review of 100 Cases
J Roy Army Med Corps 1949, Jan, v 92, No 1, 1-23, 11 figs [39 refs]

A three-stage clinical course was discernible in the majority of cases included in the investigation, (1) the initial or prodromal stage appeared with malaise, feverishness, and anorexia progressing to febrile coryza accompanied by an occasional dry cough This phase lasted from one week to a month (2) The intermediate or bronchitic stage characterised by an increasingly persistent cough commonly described as irritating, hacking or dry The duration of this stage varied from one month to three years (3) The terminal or asthmatic was the most prominent clinical phase affecting all but three patients in the series This stage varied in duration between the limits of one week and 13 years

More than 50 per cent of the skiagrams examined showed the characteristic shadows associated with this condition The most constant and prominent pathological feature of this syndrome was its remarkable eosinophilic leucocytosis, counts ranging between 1,000 and 50,000 eosinophils per cmm The severity of the symptoms was unrelated to the degree of eosinophilia, and sudden unexplained drops in the eosinophil count lasting from one to four days were occasionally noticed

Sputum was examined for mites by the method described by CARTER *et al* [this *Bulletin*, 1946, v 43, 683] Out of 67 cases examined mites were present in 42 Four genera were recognized, *Tarsonemus*, *Tyroglyphus*, *Glyciphagus* and *Carpoglyphus* Various stages in the life-cycle were seen, male and female adults, hypopion forms, nymphs, larvae and ova Eighty per cent of the patients investigated lived in an environment which exposed them to the risk of inhaling airborne mites, and 56 of them worked in ration stores, cookhouses, bakeries, grocery shops, mills or warehouses Sputum from a series of 44 controls was also examined for mites by the same technique The control consisted of three groups, 13 persons suffering from respiratory disorders not associated with eosinophilia, 17 healthy persons employed in army stores, cookhouses, etc, and 14 healthy persons selected at random

Treatment consisted of four to eight injections of arsenic in 12 cases, neoarsphenamine, tryparsonum, or acetylarsan being used once or twice weekly in doses graduated from 0.1 gm to 0.5 gm The other patients were given oral carbasone, leucarsone or stovarsol, one tablet twice daily It was found that the decline in eosinophilia continued after cessation of treatment, and prolonged dosage was therefore unnecessary

MONTESTRUC, E Un traitement pratique de la pseudomyiase rampante [A Practical Treatment for Creeping Eruption] *Arch Inst Pasteur de la Martinique* 1949, Jan, v 2, No 1, 24-6 [12 refs]

The author, writing from Martinique, discusses the literature regarding the incidence and aetiology of creeping eruption and goes on to discuss its clinical manifestations It is suggested that *Ancylostoma brasiliense* is the possible local cause Many of the treatments tried for this refractory condition are mentioned Ethyl chloride sprays are probably the most effective measures

yet known. In the absence of this substance in Martinique a trial was made with ice. Ordinary small blocks of ice from the tray of a refrigerator were applied on and around the lesion, until all the ice had melted (about 10 minutes, usually). The itching ceased almost at once. A second application was made the same day and on the next day the track, erythema and itching had all disappeared and have not recurred. This method has been confirmed with like success in several subsequent cases. Two applications daily for two days are claimed to be usually sufficient to clear the lesions completely. Such a treatment is obviously both simple and cheap. *H. J. O'D. Burke-G. ff. et.*

MÁNGUZZI R. V. & VIVAS, M. M. Apendicitis por paratubos. [Appendicitis associated with Paratubos] *Prensa Méd. Argentina*. 1948 Nov 19 v 33 No. 47 2252-3

An account of two cases. In one 1 *Enterobius* and in the other segments of *Taenia saginata* were found.

ENTOMOLOGY AND INSECTICIDES GENERAL

DAKSHINAMURTY S. The Common House-Fly *Musca domestica* L., and its Behaviour to Temperature and Humidity. *Bull. Entom. Res.* 1949 Dec., v 39 Pt. 3 339-57 6 text figs. & 4 figs. on 1 pl. [38 refs.]

The housefly is concerned in the dissemination of a number of disease organisms but, although it is well established that its abundance and activity and the incidence of fly borne diseases are dependent on climatic conditions, little is known of how these conditions affect the adult fly. The present paper is part of an extensive study of the factors controlling fly density. It is concerned with the responses of adult flies to gradients of temperature and humidity and to combinations of these two important environmental factors.

The experiments, which were carried out in a choice chamber modified from the type used by GUKK and KEXSEBY (*J. Exper. Biol.* 1933, v 13, 450) and further developed by THOMSON [this Bulletin 1938 v 33, 913] were designed on a pattern permitting the results to be examined by an analysis of variance.

In addition to the experiments arranged to investigate choice observations were made with the same apparatus on the activity of flies at four combinations of temperature and humidity.

The author first finds that the flies selected the lower of the two humidities in each of the following choices provided at 23°C. —20-40 per cent. 40-60 per cent. 60-80 per cent and 80-100 per cent relative humidity (R.H.).

In arranging the apparatus for studying their responses to a choice of two temperatures the difficulty that a temperature gradient necessarily involves a humidity gradient is met in the following way: selection is made of a graded series of acid water mixtures which provide in one experiment, a constant R.H. value but a saturation deficiency (S.D.) gradient. In a parallel experiment the mixtures are selected so that a constant S.D. prevails throughout the chamber but the R.H. varies with the temperature gradient. Thus for example a constant R.H. of 65 per cent in the gradient 20-30°C. results in saturation deficiencies of 6 mm. and 11 mm. S.D. at the temperature extremes. Conversely in this same temperature range constant S.D. of 8 mm. provides an R.H. of 53 to 75 per cent. It will be observed that each temperature extreme is associated once with the drier air (e.g. 20°C. with 11 mm. S.D.) and, in the parallel experiment, once with the moister air (e.g. 30°C. with 75 per cent

R H) Similar conditions prevail for the other temperature choices investigated, namely, 30°C or 40°C and 27°C or 33°C

It is shown that flies, when given a choice of 20°C or 30°C and 30°C or 40°C chose 30°C regardless of whether this temperature is coupled with the drier air or the more moist air

The first demonstration—that at 25°C flies selected the drier air in the four humidity ranges offered—is then confirmed at 25°C and 35°C (mean values of the two temperature ranges) in experiments in which the humidity ranges were limited to those investigated at 20–30°C and 30–40°C. The choice was again for drier air

An experiment is then made suppressing the temperature factor. A limited range of 27° to 33°C is found to be suitable and humidity ranges are offered of 10.6 mm to 15 mm S D (R H = 60 per cent throughout the chamber) in one experiment and, in the parallel test, 50 to 60 per cent R H (S D = 13 mm throughout the chamber). The flies chose again the drier atmosphere, namely, 15 mm S D at 33°C and 50 per cent R H at 27°C. It is concluded that, provided there is not a temperature gradient great enough to induce a reaction to temperature, flies select the drier air. It appears from this type of result also that it is not possible to decide whether houseflies choose by the R H scale or the S D scale. This is the author's conclusion although (p. 350) he notes that there is a statistical indication that the choice of humidity is dependent on the S D scale.

These responses are next related to activity as observed in four separate experiments on flies at 35°C and 18°C, each temperature being tested once in association with 20 and once with 90 per cent R H. Flies were found to be most active at 35°C and 20 per cent R H, least active at 35°C and 90 per cent R H, intermediate, and similar, in activity at 18°C and each of the humidities. That is, at the low temperature, humidity had no effect on the flies' activity, but at a high temperature activity occurred particularly in the dry air and was slight in the sub-saturated air.

In an interpretation of these results it is suggested that flies, since they select dry air, must have an efficient spiracle closing mechanism and be able to absorb water from their faeces before its passage. It is known, the author points out, that metabolic rate is a function of temperature and that higher temperatures involve an increase in the metabolic rate with need for loss of excess metabolic water. In dry air this is assured because the increased respiration rate of the fly provides facility for evaporation of water in the tracheal tubes through the open spiracles; this physiological mechanism assists, it is supposed, in keeping the body below the environmental temperature. In a highly humid atmosphere at high temperatures this cooling effect cannot take place since the evaporative power of the air is inadequate. A fly might therefore die in these circumstances owing to the direct effect of temperature, and certainly can become inactive (e.g. at 35°C and 90 per cent R.H). In dry air at high temperature (e.g. 40°C) there is, however, risk of desiccation and the fly therefore prefers air at a lower temperature (e.g. 30°C) at which an adequate metabolic rate and activity can still be maintained and at which, even if more moist than the air at 40°C, loss of metabolic water is still possible. Cooling of the body can therefore still occur and the risk of desiccation is less. At low temperatures (18° or 20°C) the metabolic rate is reduced correspondingly and with the lower respiration rate there is only limited opportunity for loss of water through the spiracles. Consequently, flies at lower temperatures are only moderately active and, furthermore, humidity can play little part in affecting this activity. Flies, therefore, go towards the higher temperature of 30°C where the metabolic rate and activity are increased. They would prefer a drier air but will again tolerate a

more moist air than at the lower temperature provided this is consistent, as it is at least at 75 per cent. R.H. with the need to get rid of the excess metabolic water. In circumstances where this is not possible a dropical condition is presumed to develop.

These interpretations are related to general observation on fly activity and density in the field. Hot dry conditions such as occur usually from 10 to 4 p.m. daily are associated with maximal fly activity. The tendencies of flies to be outdoor insects on hot sunny days and to come indoors in rain are considered to be a choice of the warmer and drier atmosphere. In temperate climates flies are most abundant sometime during the summer and this is a temperature effect but in the tropics differences of humidity related to rainfall incidence are more important than temperature which is generally suitable for flies at all times of the year. Examples are cited of flies being numerous and active in hot, dry inland areas (e.g. Delhi) but fewer and less troublesome in warm humid coastal cities (e.g. Madras, Calcutta, Bombay) or in the humid climate of Malaya. In the first case activity and abundance are associated with high temperature and low humidity. In the humid regions although the temperatures are suited to activity the humidity is too high the fly activity is limited, its reproductive potential lowered and its numbers therefore are less.

These observations are made with due regard to the incidental but important effects of climatic conditions on other aspects of the flies' biometrics.

Twinn, C. R., Hocking, B., McDuffie, W. C. & Cross, H. F. A Preliminary Account of the Biting Flies at Churchill, Manitoba, Canada. *J. Res. Sect. D Zool. Sci.* 1948 Dec. v. 28, No. 6 334-57 14 figs. [16 refs.]

At the request of Canadian and of United States Government Department the authors carried out a survey of the biting flies in the neighbourhood of Churchill, Manitoba, with a view to devising control measures. The survey covers the period May 16th to August 10th, 1947.

Churchill in the subarctic region, lies at the mouth of the Churchill River on the west shore of Hudson Bay. The terrain is varied and the following types of country occur: spruce-larch forest, shrubby willow-birch associations, tundra and tundra meadow extending to the tidal flats and sand dunes of the Hudson Bay shore.

The snows melt about May and numerous ble pools and much marshy ground persist throughout the spring and summer. The river is free ice about mid June. The average monthly figures for climate in May, June, July and August were respectively: temperature 74.5°F, 44.8°F, 48.3°F and 54.3°F; relative humidity 91.5 per cent. in May and 84 per cent. from June 1 to August; windspeed—11 to 14 m.p.h.; rainfall—0.15, 0.91, 0.94 and 4 inches; cloudy condition prevailed for about half the time.

Mosquitoes—No anophelines are recorded. *Aedes triseriatus*, 4 species, 1 nearcticus, 1 communis, 1 confusus, 1 excrucians, 1 flavescens and 1 cinctus occurred in that order in abundance breeding in the various pool and marshy ground. All overwinter in the egg stage. Adult emergence at a peak about the end of June; biting activity is maximal about mid July but by early August mosquitoes are practically less in number. Biting occurred chiefly from sunset to sunrise but forest species would bite in the day time. Females of several species have been found carrying the pollen of orchids (*Isotria medeolae*) on their heads. It is suggested that the mosquitoes in feeding on the nectar of orchid effect pollination. *Culiseta inornata* and *C. impatiens* were few in number. Details are given under species concerning places and habits of all ten species.

Simuliids—The following species are recorded —*Simulium venustum*, *S vittatum*, *S ottawaense*, *S arcticum*, *S perissum* and *Lusimulium baffinense palens*, *E latipes* and *E aureum* together with four possibly new to science. *S venustum* is the most important blackfly pest of man, breeding in ditches, drains and rivers. It is thought to overwinter in the egg stage at Churchill. Adults are very numerous by mid-July. Eggs, larvae and pupae occur into August, there being probably three generations each summer. Detailed notes are also given for *S vittatum*, *E latipes*, *E aureum* and the new (unnamed and undescribed) species.

Tabanids—Collections were made incidentally to other work. No males or immature stages were taken. The following species were found —*Hybomitra affinis*, *H septentrionalis*, *H metabola*, *H zonalis*, *H hearlei* and *H gracilipalpis*, *Chrysops carbonaria*, *C furcata*, *C nigripes* and *C frigida*. The first two species of each genus were the most abundant, occurring from early or mid-July into August, and with *Chrysops* appearing to bite man more readily. *Chrysops* was seldom taken outside woodland. *H affinis* was attracted in large numbers to vehicles, including trains and track vehicles, settling on a standing vehicle rather than on a nearby person. It seemed that the warmth of the vehicle, which had just halted in the instances observed, was the attractant, movement stimulated pursuit. Tabanids were biting in daylight, preferably in the sun, and only above 55°F. Although often in buildings they did not bite indoors.

Suitable clothing and "a good standard repellent such as DMP" provided good protection against tabanids. Accounts of control and protective methods against these biting fly pests are to be published elsewhere. D S Bertram.

BOHART, R M. A Synopsis of the Philippine Mosquitoes. Named No 580, [1+388 pp., 10 pls [33 refs] multigraph [Washington, D C] Dep. Navy, Bur Med Surg [1945] [Summary taken from *Rev Applied Entom* Ser B 1949, Jan, v 37, Pt 1, 10]

This paper contains keys to the mosquitoes found in the Philippine Islands, together with notes on the morphology and distribution of most of them, the synonymy of some and the breeding place where known. Tables are included showing the Philippine species of *Anopheles* that have been incriminated as natural or experimental vectors of malaria.

MARKS Elizabeth N. Studies of Queensland Mosquitoes. Part III. The *Aedes* (*Finlaya*) *australiensis* Group. Univ of Queensland Papers. Dept of Biology 1948, Aug 16, v 2 No 8, 42 pp., 17 figs.

BOHART, R M. A Key to the Chinese Culexine Mosquitoes. Named No 961, 23 pp., [19 refs], multigraph. Washington, D C, Navy Dep, Bur Med Surg, 1946. [Summary taken from *Rev Applied Entom* Ser B 1949, Feb, v 37, Pt 2, 27-8]

Keys are given to the adults and larvae where known of the mosquitoes that occur in China, excluding *Anopheles*. Very brief notes are included on their distribution within and outside China, together with indications of the species that are natural or experimental vectors of disease in China or elsewhere.

BROUHAERT J. *Aedes aegypti* (Linnaeus) the Yellow Fever Mosquito in Arizona (Diptera). *Bull. Brooklyn Entom. Soc.* 1917 v. 41 No. 3 157. [Summary taken from *Rev. Applied Entom.* Ser. B. 1919 Feb. v. 37 Pl. 22.]

In a recent monograph *Aedes aegypti* L. was not recorded from Colorado Utah Arizona or California. However J. R. de la Torre-Dueno recently sent the author a male caught in his house at Tucson Arizona in October 1946 and stated that the species is well known in that locality where it is fairly common in summer and often annoying indoors through its attack on the ankles. It often bites during the day. If temperature conditions are favourable breeding continues during the winter.

FAIRCHILD C. B. & HEATH M. An Improved Method for Mounting Small Insects. *Science* 1948 July 2, 70-71

The following method of mounting specimen of P. var. 1914 was used: the authors and found to be more satisfactory than many others that have been tried.

The head, thorax and abdomen are separated and briefly boiled in 10 per cent. KOH. Alternately the insect may be gently warmed or be left for some hours in cold KOH. (The wings are not treated with KOH but are put straight into the stain.) The specimen is next rinsed in water and then stained with acid fuchsin in phenol for twenty minutes. After at least 1 hour it is rinsed in phenol and mounted on a cover slip in separate drops of phenol copal, or Canada balsam dissolved in pure phenol and left overnight.

In the morning the cover slip is turned over and a large drop of phenol copal on a slide. The cover slip should be supported at the corners by chips of cover slip glass to avoid crushing of the specimen. The preparation should now be dried in gentle heat.

In making preparations of the abdomen of female Phlebotomus the change from pure phenol to the mounting medium should be made in gradual stages.

It is pointed out that the spermathecae are best seen either in phenol or in water after the KOH treatment, and drawings should be made at this stage, as even with most careful mounting it is not always possible to avoid distortion

A general review and discussion

BISHOPP, F C The Medical and Public Health Importance of the Insecticide DDT. Hermann M Biggs Memorial Lecture *Bull New York Acad Med* 1945, Nov v 21, No 11, 561-80 [22 refs]

FAY, R W, BUCKNER, A J & SIMMONS, S W Laboratory Evaluation of DDT Residual Effectiveness against House Flies, *Musca domestica* *Amer J Trop Med* 1948, Nov, v 28, No 6, 877-87, 6 figs

The residual effectiveness of DDT was tested by exposing three-day-old adult houseflies to treated panels forming the walls of a chamber

Normal ageing of panels with DDT deposits did not reduce the toxicity, but panels exposed to insects at frequent intervals showed a marked decrease in toxicity over periods up to 52 days The theory that this decrease in toxicity might be due to a mechanical removal of DDT by flies was tested by making a quantitative chemical analysis at the beginning and at the end of the experiment Although the mortality of flies was reduced from 75 per cent to 0 per cent over four months, the quantity of DDT was reduced only from 200 mgm/sq ft to 158 mgm/sq ft

Male houseflies were shown to be less resistant to DDT residues than female flies and since the ratio of the sexes varies considerably in different localities this difference is important in a field evaluation of DDT residual effectiveness

DDT was found to penetrate a roughwood surface more readily than plywood or wallpaper Owing to the loss of toxic residues accompanying absorption of DDT into a surface, a 2½ per cent DDT emulsion is normally used instead of a smaller volume of 5 per cent DDT Experiments in which 2½, 5 and 10 per cent DDT is used to give deposits of 200 mgm/sq ft in each case, on the three types of surface showed that 2½ per cent DDT was more effective than other concentrations on wallpaper and roughwood, but that there was no significant difference on plywood The residual effectiveness was much better on roughwood than on the other two surfaces

Panels treated with a DDT emulsion and others with a DDT water-wettable suspension were exposed to sun, or rain, or to sun and rain The emulsion residues were not affected, but the water-wettable suspensions deteriorated after five weeks' exposure to sun and rain, and after twelve weeks' exposure to rain alone

LINDQUIST, A W, KNIPLING E F, JONES, H A & LAAKE, E W Blow Fly Control with DDT Sprays dispersed from Aircraft *J Econom Entom* 1948, Dec, v 41, No 6 971-3

ROMANA C & ABALOS, J W "Control" larvario de simuliidos y culicidos con Gammexane y DDT [Larval Control of Simuliids and Mosquitoes with Gammexane and DDT] *An Inst Med Regional Tucuman, Argentina* 1948, Dec, v 2, No 2, 107-46, 9 figs English summary

The authors describe the survey and treatment of twenty-one streams, which was carried out by one man, in a zone having an area of 75 sq km in

Argentina. The insecticides used were crystallized DDT dissolved in kerosene at the rate of 50 gm. insecticide per litre of solvent and Gammexane (benzene hexachloride—BHC) in wettable mixtures.

The minimum dose of Gammexane necessary for the elimination of *S. malin* is given as 700–1,000 mgm. per litre of water. A detailed account and tables are given of the observations and treatments of streams over one year.

Previously treatment against *Anopheles Culex* and *Simulium* in this area involved the clearing of vegetation along the streams and treatment with petroleum. This was efficient against *Anopheles* but not against *Simulium*. Moreover treatment with BHC requires less labour and thereby is 85 per cent. cheaper than the other method. Although treatment with DDT and BHC is simple and efficient it is practicable only when streams are of small or medium size.

It was observed that BHC also killed crustaceans and snails which are intermediate hosts in the life cycle of certain helminths. C. M. Harrison

MAIER J. REYDORFF R. C. & SCHLITZ, M. The Duration of Residual Effect of DDT Sprays on Building Materials used in Rural Venezuela. *Amer. J. Trop. Med.* 1948 Vol. V 28 No. 6 889–94

Three types of spray were tested —

- (1) 5 per cent. suspension in water of DDT 50 per cent. wettable powder
- (2) Emulsion in water of xylocel-Triton X 100 DDT concentrate
- (3) 2.5 per cent. solution of technical grade DDT in refined kerosene

Blocks of five common types of building material were sprayed at 1 gm. sq. metre (approx. 100 mgm./sq. ft.) blocks of *adobe* (sun-dried mud) *l. baroque* (sun-dried mud mixed with straw) *cucalado* (adobe with a coating of lime and water) *gambule* (thatching of coarse flat leaved grass) and *paja de cerro* (thatching of fine round leaved grass).

Wild engorged female mosquitoes were exposed to these blocks at monthly intervals, for periods of fifteen minutes and four hours.

After fifteen-minute exposures the aqueous suspension of DDT gave 100 per cent. mortality on all wall material in the first month and continued to do so on *cucalado* up to the fourth month, but on *adobe* and *l. baroque* gave only 40 per cent. and 45 per cent. mortalities respectively after three months. The emulsion and the solution were found to be less effective than the suspension although on *adobe* their effectiveness increased over the first three months. In the test on roofing material the suspension and emulsion gave approximately similar results but the DDT solution gave much lower mortalities.

Differences between the three types of spray evident in the fifteen minute exposure tests were not borne out by mortality counts 1 mosquito after four-hour exposures. Mortalities 17%–100 per cent. were obtained on material sprayed nine months previously and *cucalado* gave a 100 per cent. mortality after ten months.

The authors point out that under natural conditions mosquitoes are not likely to remain in contact with a treated surface for a period of four hours and that the result of the fifteen minute exposures probably gives a more accurate picture of the practical effect of spraying houses. C. M. Harrison

REPORTS, SURVEYS AND MISCELLANEOUS PAPERS

VAN DEN BERGHE, L. Un nouvel Institut Belge pour la recherche scientifique en Afrique centrale [A New Belgian Institute for Scientific Research in Central Africa] *Acta Tropica* Basle 1949, v 6, No 1, 51-2

In July 1947, the *Institut pour le Recherche Scientifique en Afrique Centrale* (I R S A C) was established in Léopoldville. The object of the Institute is the fundamental study of tropical conditions from the human, zoological and botanical aspects. For this purpose, the Belgian Congo is particularly well suited, because of its varying altitudes and dense network of communications.

In 1949 and 1950, several research centres will be erected in the Congo and in Ruandi-Urundi, where Belgian and other scientists will have facilities for pursuing their researches. These will include centres for experimental biology, anthropology, climatology, botany and nutrition.

The Institute will have its own scientific staff and equipment and will serve to co ordinate and extend the work of the different scientific institutions in the Congo. It will also serve as an information bureau and organization service for visiting scientists. It is claimed that the library to be established at the main centre will probably be the largest in Central Africa.

The I R S A C will not produce a periodical of its own, but its annual scientific reports will contain extracts from notes or publications by its members. These annual reports will be widely distributed throughout the scientific institutions of the world.

The Institute is administered, under Government sponsorship, by an Administrative Council, consisting of representatives of different branches of science. It is noted that, in addition to leading Belgian scientists, the Council includes three eminent foreigners, namely Dr E. B. Worthington (Scientific Adviser to the East African High Commission, Nairobi), Professor M. A. Chevalier (of the National Natural History Museum of Paris), and Dr Harlow Shapley (Director of Harvard College Observatory).

The Director of the Institute, who is already in the Belgian Congo, is Professor Louis van den Berghe, of the Tropical Medicine Institute in Antwerp and Tulane University.

GREAVES, F. C. The Health Services Program in the Trust Territory of the Pacific Islands. *US Nav Med Bull* 1948, Nov-Dec, v 48, No 6, 925-40, 7 figs (1 map)

The Pacific islands to which the author refers are those of the former Japanese Mandated Islands of Micronesia, they include 2,133 islands, atolls and reefs, in the Marshall, Caroline and Marianas Groups. There are about 50,000 inhabitants, who live in about 120 isolated island communities. Before contact was established with foreigners there were about three times as many people, but a century and a half of contact has meant epidemics of typhoid fever, smallpox, measles and other diseases, which displayed the severity commonly recorded in unsalted populations. At present there is little accurate information as to the prevalent diseases, though there is reason to believe that tuberculosis is widespread and intestinal parasitism almost universal, leprosy and venereal diseases also exist, and there is a form of encephalitis due to an unidentified virus, which would repay study.

In these islands there are civil administration dispensaries, with 325 beds and 18 medical officers, but the Guam Memorial Hospital of 300 beds can also be used, though Guam is not administratively part of these island groups. The American authorities have equipped a survey ship, which carries two medical officers, a dental officer, a public health official and their staff and equipment.

(including a photofluorographic unit). This vessel travels from island to island, all the inhabitants are examined and an assessment of the sanitary conditions is made. Eventually a considerable body of exact information will be available on which the structure of a health service can be based.

The training of the local people for health duties is promoted, and there are three schools, for medicine, dentistry and nursing respectively, at which the courses last 4 years. The people are lively and intelligent, and are "quick to accept the elements of civilization that benefit them, interest them, or amuse them."

The American authorities (presumably the naval authorities) have interpreted the Trusteeship Agreement literally, and have proceeded upon a course of action based upon accepted American standards. That is they do not propose to leave the people undisturbed, and to take only such health action as would be necessary to protect the American administrators, but rather to train the people to the adoption of American standards. Progress is being made in cleanliness, of villages, safety of food and water supplies, sanitation, etc.

[It will be interesting to see the reports of the medical survey when these are published. Before the war there was little information about these islands.]

Charles H. Stock

HARDING R. D. A Note on some Vital Statistics of a Primitive Peasant Community in Sierra Leone. *Population Studies* 1948 Dec. 1, No 3 373-6.

This paper records the results of thorough and repeated examination of all persons in a community originally numbering 1,408, living in primitive conditions in Sierra Leone: the examinations which were made in the course of an investigation into the manifestations of untreated yaws were repeated every two months for a year. The accuracy of the figures obtained is high, for almost the whole work was done by the author and his wife who soon knew the individual persons by sight and who usually succeeded in tracing absentees. Report of death were cross-checked as far as possible and are regarded as fairly accurate.

Among the 1,408 persons there were 29.3 per cent of men (over 15 years), 38.2 of women (over 15), 18.6 of boys and 16.0 of girls: this distribution corresponds with that of other communities in rural Sierra Leone. There were dispensaries within 15 miles of all the people but they were used mainly for trivial complaints and there was therefore little chance that medical interference had greatly influenced the statistics obtained except that the death rate from sleeping sickness had been reduced. The annual birth rate was 32.9 per 1,000 (± 3.77), the miscarriage and still-birth rate 22.9 per 100 live births, the death rate 78.4 per 1,000 (± 3.53) (there were no major epidemics) and the infant mortality rate was 417 (± 49) per 1,000 live births.

Of the total deaths (56) almost half were in children aged 3 years or less (26) of these 26, 10 were attributed by the relations to acute fever, probably malaria in most cases. An acute diarrhoeal disease, probably bacillary dysentery, caused 9 deaths. These figures may be compared with others previously recorded by the author [in a paper reviewed in this *Bulletin* 1940, 37, 697].

Harding makes the point that reasonably accurate vital statistics are necessary before satisfactory health plans can be made and suggest that small investigations such as he has made should be undertaken as often possible together: they would create a reliable body of evidence. This is of course very sound: it seems likely that missionary communities which are relatively stable would be able to contribute most useful information if they set out to obtain it.

WEST, J B **United States Health Missions in Liberia** *Pub Health Rep* Wash 1948, Oct 15, v 63, No 42, 1351-64

This review relates to a period of 3 years, from November 1944, during which the Missions were at work in Liberia. The first duties were to ensure the good health of the American forces. The author gives some account of the medical services of the country and of the common diseases.

There were two hospitals at Monrovia, with 60 beds in all, not well equipped. The Firestone Plantations Company maintained a modern hospital of 100 beds near Roberts Field. There were 6 physicians and 2 dentists in Liberia, for a population of 2 millions.

The chief diseases are malaria, helminth infections, venereal diseases, and trypanosomiasis. The author makes the remarkable statement that "98.6 per cent of the mosquitoes aspirated from inhabited areas [of Monrovia, Kahata and Roberts Field] were *A. gambiae*", the remaining 1.4 per cent including other anophelines, *Culex fatigans* and *Aedes aegypti*. He describes the control measures adopted, which consisted largely of DDT residual spray and DDT in oil as a larvicide. In the three years there has been a great decrease in the number of cases of malaria treated in hospital. Chloroquine was available. The measures taken to cope with intestinal and venereal diseases are also described.

[The report is a small addition to our knowledge of the health situation in Liberia, but it is only a sketch.]

Charles Wilcocks

POINDESTER, H A **Experimental Animal Colony in Tropical West Africa** *Pub Health Rep* Wash 1949, Jan 14, v 64, No 2, 57-62

An account is given of an attempt to found a small laboratory animal breeding unit in tropical West Africa. The area chosen for the project was Monrovia in Liberia, at sea level.

The animals with which the colony was commenced came from the National Institute of Health Laboratories, Bethesda, Maryland, and consisted of 9 white rabbits, 16 guinea-pigs, 12 white rats and 18 white mice, the exact proportions of the sexes are not given.

On arrival of the animals at Monrovia, they were accommodated in cages in a well-built and well-ventilated animal house. Apparently there were accommodated in the same animal colony, local fauna of all sorts, including dogs, cats, wild rats, shrews, chickens, canaries, reptiles, frogs, fishes and others and all were fed on local products.

The resulting "tragedy" of an outbreak of *Salmonella typhimurium* infection to say nothing of the lesser ills described, should surely have caused no surprise under these conditions.

The next tragedy was cannibalism among the mice, guinea-pigs and rabbits. Apart from these positive deterrents to multiplication, the rabbits and guinea-pigs refused to breed, although they appeared healthy. The possible causes of this sterility are discussed without much light being thrown on the subject.

As a last resort, a few rabbits and guinea-pigs were transferred to Ganta, which is at an elevation of 1200 feet. The food given here was similar to that given at Monrovia, with the addition of elephant grass.

In the case of both rabbits and guinea-pigs, the breeding results were highly successful in this new location. New rats imported from the United States bred well at Monrovia as did the white mice originally imported.

From the general account of these breeding operations, it is evident that at least some of the trials and tribulations encountered were due to inexperience and could have been avoided by the application of knowledge already possessed.

by others long experienced in the care of laboratory animals in the tropics. In the discussion (4 lines) it is stated that "cross breeding of the temperate zone experimental animals with native stocks seem to be indicated." (There is nothing in the account to show how this conclusion even if correct is arrived at unless the addition of two female and one male rabbit obtained in Liberia and sent to Ganta, supplies the evidence for this generalization.)

COOBNOR. The Pasteur Institute of Southern India, Coonoor. Annual Report of the Director together with the Forty-First Annual Report of the Central Committee of the Pasteur Institute Association 1947-48. 48 pp. 1 chart. 1948. Madras. Diocesan Press.

This report follows on the same lines as that for 1946-47 (this *Bulletin* 1948 v. 45: 657).

During the year 18,551 patients received the Institute's anti-rabic vaccine either at the Institute or at Subsidiary Treatment Centres. At the former 323 patients received a complete course and 61 received incomplete courses of treatment. There was one death. At the subsidiary centres 13,930 patients were treated (8,799 complete courses). There were 11 deaths among these all occurred among Asiatic patients who had been exposed to dog bites. In Madras and neighbouring states 1,321 animals were also treated and these included 855 dogs. Detailed statistics relating to rabies are shown in 10 tables.

The research work in the Institute and the Nutrition Research Laboratories includes a number of studies already noted in this *Bulletin* and the *Bulletin* of *H. 1948*. These investigations included work on rabies virus and vaccines, growth requirements of *V. cholerae* in media and tropical eosinophilia in experimental animals. Work was also done on the vitamin B complex, vitamins A and D hydrogenated oils, erythrocyte phosphatase, metabolic disorders of the liver and experimental lathyrism.

A Nutrition Clinic was established in 1947 and 219 cases of nutritional disorder were examined during the year. They are classified in a table in the text.

In the Southern India Branch of the Malaria Institute of India *Plasmodium gall narium* and insect vectors were maintained. Attempts to preserve *P. gall narium* by drying infected blood in vacuo were unsuccessful so far as infection experiments were concerned, a thin dried blood could not be re-dissolved in saline or fresh serum. The parasites appeared, however, to retain their morphological structure.

Experiment are in progress toward infecting partially incubated duck embryos through the chorio-allantoic membrane with varying quantities of blood from fowl acutely infected with *P. gall narium*. Studies on the biochemistry of *P. falciparum* were completed.

STRANUS, J. H. Reflections on the Course of Preventive Medicine in Malaya. *Med. J. Malay*. 1948 June v., No. 4: 221-38.

The presidential address delivered at the Annual Meeting of the Malaya Branch of the British Medical Association deals with the history of the impact of western medicine on Malaya. In the early years curative medicine monopolized attention. A Port Quarantine Service was established in 1900 but serious attention to preventive medicine had to wait till 1911 when the Health Service of the then Federated Malay States was founded. Rubber cultivation, increasing prosperity and disease prevention yielded increased dividend. The address provides much interesting information about Malaya of people and

their diseases, and the efforts made by research workers and health departments to control disease prevalence during the last 28 years this does not lend itself to summary For the future, outstanding tasks include the application of recently acquired knowledge and techniques to the control of malaria, an all-out attack on tuberculosis, much more attention to nutrition and deficiency diseases, and an orientation of the work of the Health Services towards social medicine

HARRISON, J L *A Key to the Squirrels of Malaya* Reprinted from *Malayan Nature J* 1948, Dec, v 3, No 4, 201-9, 4 figs on 1 pl

EDDEY, L G *An Example of Effective Disease Control in a Tropical Mining Community* Reprinted from *Brit Guiana Med Ann*, 1947 1948, 162-81, 6 figs

This short report is written by Eddey, but he makes it clear that the work described was initiated and carried out by Dr Michael Kenney, who "could not be persuaded to publish an account of these methods" Kenney was Resident Physician to the Kwakwani settlement of the Berbice Company, engaged in the mining of bauxite on the Berbice river in British Guiana This settlement differed from many others in its cleanliness and good appointments, and the credit for this state of affairs goes to Kenney who, from 1943 onwards, had made it his business to introduce improvements on a large scale He first instituted the routine of periodical examination of all the workers and their families (total about 400 persons), keeping adequate records and giving adequate treatment The examinations included bi-monthly blood examinations, and monthly stool examinations, but as conditions improved these intervals were modified In the early stages there was some difficulty over attendances, but this did not last long

At first the workers were not well housed, but Kenney made good housing, with efficient mosquito screening, one of his main objectives, and he introduced bed-nets In the early days of screening, some of the houses became traps in which large numbers of *Anopheles darlingi* or *A. aquasalis* could be found, with a very high rate of infection, but improvements were made so thoroughly, and the people were made to understand the matter so well, that soon the houses were largely mosquito proof [But it seems to the reviewer that this must have required much tireless supervision] DDT was used, and the more permanent antilarval methods were executed, the result was a great reduction in the number of anophelines captured

Hookworm infestation and filariasis constituted serious problems, but they were dealt with as vigorously as malaria, the former by treatment and sanitary measures the latter by anti-mosquito measures Food and water supplies were regulated Records show that from 1944 onwards the numbers of people given treatment in or out of hospital fell very considerably, as health conditions improved there was no slackening in the medical service given One interesting feature of the work was the formation of an elected Employees' Health Committee whose function was to take a direct share in the welfare of the settlement

[Altogether a notable achievement]

Charles Walcocks

BOOK REVIEWS

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE SECTION ON MEDICAL SCIENCES. Rickettsial Diseases of Man. A Symposium on the Rickettsial Diseases of Man, organized by the Section on Medical Sciences of the A.A.A.S., and presented at the Boston Meeting on December 26-29, 1948. Organized by M. H. SOUTER. Edited by F. R. MOUTON. 47 pp. 24 figs. & 3 maps. 1948. Washington 5. American Association for the Advancement of Science 1515 Massachusetts Avenue N.W. [16.25 37 B.]

This collection of 27 papers by 27 distinguished U.S.A. workers forms a very important contribution to knowledge of the rickettsial diseases of man. Special prominence is naturally given to the work of American investigators but the authors have by no means neglected the work of experts from other parts of the world, so that the book provides a concise comprehensive critical, and fully documented, review of the fresh knowledge of the subject that has been acquired during the years of World War II and up to the end of 1948. The papers were read in 1948 so that the date of publication, 1948, is likely to give rise to misunderstandings.

Apart from trench fever to which only a few casual references are made, all the known rickettsial diseases of man are dealt with from the points of view of epidemiology, aetiology, diagnosis, treatment and prevention.

Bull's fever is referred to as not having been proved to be a rickettsial disease.

Although most of the subject matter has been published elsewhere its presentation in the form of collected papers will be greatly appreciated by all workers on the rickettsial diseases, especially as many references are made to reports which have not been published.

The first paper by S. HARAR, Jr., as Director of the U.S.A. Typhus Commission, deals with Epidemic Typhus in the Mediterranean Area during the last War. Some sidelights are thrown on the dramatic story of the control of the 1943-44 epidemic in and round Naples but a final review of the subject is said to be impossible owing to the occurrence of serious differences of opinion with regard to the contributions made by the various persons and organizations concerned in the operations. It appears however that the workers chiefly responsible for initiating the method of personal delousing, employed in more than three million instances, with DDT were members of the Rockefeller Foundation Team including J. A. FRANKEL, F. J. SORRE and C. M. WATFORD, the last named of whom was actually serving with the Typhus Commission while on leave from the Foundation. Apparently the first trial of hand blowers was made in Mexico early in 1943 presumably by Rockefeller Foundation workers and it seems only right that the worker or workers who first devised the simple but revolutionary method of dusting fully clothed persons should receive recognition.

The paper on Louse-Borne Typhus in Europe during the war is by J. E. GORDON. The epidemics in Japan and Korea are described by A. B. SCOTT, Jun. K. F. MAXCY gives a vivid account of Scrub Typhus among the U.S.A. troops. Between August 1942 and December, 1943 there were 937 cases with 53 deaths in the American bases in the Pacific. Among the troops landed at Owl-Bank in Dutch New Guinea between June and August 1944 there were 1,409 cases with only seven deaths up to December of the same year.

In the India-Burma theatre between November 1943 and July 1945 there were 695 cases with 58 deaths among American troops.

The paper by J. H. DIXON on Outbreak of Q Fever during the War completes the description of the manner in which the rickettsial diseases affected the military forces of the U.S.A.

Clinical aspects of the fevers of the typhus group are dealt with in papers by A YEOMANS (louse-borne typhus), T E WOODWARD (murine typhus), R R PARKER (Rocky Mountain spotted fever), and F G BLAKE (scrub typhus).

The excellent article on Treatment of the Rickettsial Diseases, by J C SNYDER, was written before the discovery of the remarkable efficacy of chloromycetin.

D GREIFF, gives a critical summary of all the important work on the Biology of the rickettsiae. His view is that the organisms represent one of the earlier stages of the adaptation of pathogens to intracellular life, retaining their bacterium-like morphology and probably also some independent metabolic activity, while refusing to grow in cell-free media and failing to survive in dead cells.

H PINKERTON discusses the Classification of Rickettsiae and Rickettsial Diseases. He recognizes five main groups of the diseases in man —(1) Typhus (human and murine), (2) Spotted Fever (including boutonneuse fever, rickettsialpox? and any other strains?), (3) Tsutsugamushi disease, (4) Q Fever, and (5) Trench Fever? [The question marks are inserted by the author.] Trench fever is listed "only tentatively as a rickettsial disease." This sceptical attitude is not likely to be shared by many European workers.

The author refers to the reviewer's provisional classification of the typhus-like fevers according to the known transmitting vectors. This was originally proposed in 1921, not 1943 as stated by the author, it is described as "admirably simple and implying certain important epidemiological truths", and as being "the most difficult to disregard", but he finds it open to many serious objections "notably the suggestion that the three diseases are fundamentally more closely related than they actually are." Curiously enough this objection is completely refuted in a later paper in the present series by G B WOLBACH, the father of modern research into the typhus fevers, who writes "Rocky Mountain spotted fever, typhus and tsutsugamushi disease constitute a unique disease group when considered in the light of many common features—arthropod transmission, rickettsial etiology, clinical characteristics, and pathology." Wolbach also refers to the diseases as "the tick-borne, the louse-borne, and the mite-borne rickettsial diseases."

The author's other objections to the classification are (1) "the difficulty of substituting these terms for others which are in established usage" but the fevers are repeatedly called tick-borne, flea-borne, louse-borne, and mite-borne, and all of them have often been called typhus. (2) "That flea typhus, which is only a variety of louse typhus would be distinguished as sharply from the latter as the very different disease, 'tick typhus'." There is, however, a very real difference between flea-borne and louse-borne typhus, the former is primarily a disease of lower animals, a "zootic" disease, and so is closely related to tick typhus and sharply different in this very important respect from louse typhus which is a human, "demic", disease. (3) That "Q fever could not reasonably be called tick typhus", but why should it be so called?, it is not typhus-like and as Wolbach points out "it stands apart in its pathology". (4) That "the recently discovered rickettsialpox would make the term mite typhus ambiguous". Here again rickettsialpox is not typhus-like in its clinical features and so does not qualify for admission to the typhus group.

The author's use of the name spotted fever for the sub-group of tick-borne typhus fevers is open not only to the objection stated by himself, that the name has been given to meningococcus meningitis, but also because it is a literal translation of *Fleckfieber*, the German name of louse-borne typhus, and so is sure to cause the same confusion as has arisen in connexion with the German use of the name *Typhus* for typhoid fever.

In his discussion of the classification of the rickettsiae the author makes the following remark which will meet with general approval. "It therefore

2. The second study relates to the problem of malaria, its history, transmission in the Congo, the parasites and their development, and the general principles of treatment and prevention. The chapter is in effect an exposition of the facts of the disease and of its history, and a discussion of the present-day knowledge and of the problems still awaiting solution. It could be understood by a non-medical person.

3. In the third study Schwetz returns to trypanosomiasis in greater detail. He was a young doctor attached to the hospital service of the University of Lausanne when he first read of sleeping sickness in 1902. In 1909 he went to the Congo. In this chapter he deals with the subject on lines similar to those of the chapter on malaria—transmission, the parasites, control. In this chapter also the reader will gain the true impression of his immense first-hand knowledge of the subject as well as of his great erudition. It is, as before, an exposition and a discussion written with clarity and interest.

4. In the fourth study Schwetz explains the development of the medical service of the Congo and the means devised to deal with the complex problems presented in so large and varied a country.

Charles H. Roberts

AFRICA. Handbuch der praktischen Kolonialwissenschaften. (Handbook of Practical Colonial Information.) Vol. VI Part 2, pp. xii, 675-80 Figs. 1943. Berlin: Walter de Gruyter & Co. Krankheitsgeschichten und Gesundheitswesen [DISEASES P & OTHERS]. [Incidence of Diseases and Medical Facilities.] pp. 1-308. Die Akklimatisation der Europäer in Afrika [GROUPE 3] [ACCLIMATIZATION OF EUROPEANS IN AFRICA.] pp. 309-338.

This volume published during the war is but one of a series produced under the patronage of General Ritter von Epp and under the editorship of Dr. Erich Obst, Professor in the University of Breslau. The purpose of this book, as set forth in the introduction, is to describe the geographical pathology of Africa. Many of the statistics it is admitted are compiled on rather insecure grounds as comparatively few comprehensive microscopical surveys of this great continent have actually been carried through. The book before us therefore represents a very ambitious project and has been undertaken with consideration of the vast array of literature concerned.

It would serve no useful purpose to follow the articles in detail. They are composed on rather familiar lines and comprise many statements which owing to the lapse of time have become out of date. Under malaria, for instance, statistical tables presenting the estimated number of malaria cases per annum and the number of fatalities for various countries in the Dark Continent, and further details are given in an account of the status of malaria and black-water fever in each particular country or colony. Trypanosomiasis, kinasomiasis, relapsing fever, yaws, ulcers, trypansomiasis, leishmaniasis and rat-bite fever are handled in the same manner and distributional maps are included. The difficulties already mentioned are multiplied in dealing with intestinal infections, particularly the dysentery group. Even under the most civilized and organized conditions the exact differentiation of amoebae from bacillary dysentery is difficult enough, so that figures advanced in the field in this branch of an statistical service are generally open to question. Although a tremendous effort has been made to put a little front on this matter one is left wondering whether the imposing tables of the incidence of dysentery during the years 1929-1931 and comprising 686,773 cases are worth the paper they are written upon. For instance in 1931 12,024 cases of dysentery were notified from Egypt, while in the neighbouring Algeria there were only 39 and so on. Further on one reads that during the year 1929 in 75 faecal examinations no dysentery bacilli were ever found in Dar-es-Salaam. On the other hand in Zanzibar bacillary

dysentery constituted the predominant form. In 49 cultures 11 were positive (6 Shiga and 5 Flexner). In Mauritius and Réunion no attempt has been made to distinguish between the two main forms of dysentery.

These remarks by way of criticism may be said to apply to the other subjects such as typhoid, paratyphoid, plague, undulant fevers, the typhus group, yellow fever, dengue, phlebotomus fevers, worm infections, leprosy, the pock diseases, venereal diseases, avitaminoses, diphtheria, and zymotic fevers.

Medical institutions and facilities in every section of Africa are described in detail by C. SONNENSCHNEIN and some are illustrated by photographs.

The contribution by J. GROBER on acclimatization of Europeans in Africa, which occupies some 124 pages, is free from statistical errors, being based upon generally accepted data, but it is entirely spoiled for the benefit of future generations by periodic explosions of Nazi ideological propaganda. "Herrenvolk" is a word with a nasty tang and it recurs with alarming frequency. A very fine distributional map of the African continent showing the range of the main tropical diseases is appended in the cover. *P. Manson-Bahr*

PESSÔA, Samuel Barnsley [Professor catedrático de Parasitologia da Faculdade de Medicina da Universidade São Paulo, etc.] *Parasitologia Médica* [Medical Parasitology] 2nd Edition. Revised and enlarged. 997 pp., 409 text figs & 41 coloured figs on 2 pls. 1949. São Paulo. Editora Renascença S.A., Rua General Osório, 384.

The appearance of a second edition of this manual after an interval of only three years since its first publication (1946) is a testimony of its success and indicates a continued demand among workers in Brazil for a textbook of parasitology in their own language. The present edition has been revised and enlarged. In addition to the subjects dealt with in the first edition [which has been fully reviewed in this *Bulletin*, 1947, v. 44, 939], four chapters on spirochaetes have been included in the section on protozoology. The chapter on malaria contains the latest data on the exoerythrocytic stages of the parasites and describes the advances in chemotherapy (paludrine, mepacrine, etc.) made during and after the last war. In the chapter on anopheline mosquitoes an account is given of the new insecticides and repellents. The number of illustrations has been increased, including a second coloured plate depicting the haemoflagellates. Here and there mis-spellings have been noted, e.g. Prowazek for Prowazek, Fanthan for Fantham, *Leishmania braziliensis* for *L. brasiliensis*. However, these do not detract from the high standard of this treatise, which should be an indispensable guide to medical workers in South America.

C. A. Hoare

BINKHORST, C. D. *Toxoplasmosis. A Clinical Serological and Histopathological Study with special reference to the Eye Manifestations. Presentation of Twenty Cases of Proved or Presumable Toxoplasmic Retinopathy and Retinoencephalopathy with Associated Ocular Manifestations*. pp. x+163, 14 figs (3 coloured) & 6 folding coloured pls. 1948. Leiden. H. E. Stenfort Kroese's Uitgevers-Maatschappij N.V. [19s.]

Though first reported from man in 1923, toxoplasmosis has been recognized as a human protozoal disease since the appearance of the work by WOLF and his co-workers in 1939. During the last decade numerous contributions to this subject have appeared, indicating that human toxoplasmosis is probably cosmopolitan in its distribution and that the incidence of the disease is considerably higher than the several dozen clinical cases hitherto recorded. The use of serological methods of diagnosis has brought to light the widespread

occurrence of symptomless infection amounting according to Saldin to about 10 per cent. of the population.

However our knowledge of this disease is still fragmentary especially regarding its mode of transmission and epidemiology.

This book is divided into two almost equal parts. In the first part the author gives a detailed review of our present knowledge of toxoplasmosis. A description is given of the causative organism as it appears in man and other animal together with a host list. The available facts regarding the mode of transmission of toxoplasma are discussed, and a chapter is devoted to the various methods of diagnosis of toxoplasmosis—parasitological, serological and clinical. This is followed by a very complete account of all reported cases of toxoplasmosis in man including those in which the diagnosis was confirmed parasitologically, those in which it was based on the neutralization test and those diagnosed clinically. A separate chapter is devoted to ocular lesions, ocular symptoms associated with positive serum test and cases suggestive of this disease. A short account of the effect of drugs in toxoplasmosis concludes the first part.
